Introduction

Organ replacement has long been a source of concern for humans. In particular, needs in the field of bone tissue engineering are currently increasing especially because of the aging population and the democratization of extreme sports. Bone-grafting procedures annually performed in the world are estimated at about a few million (Bohner *et al.*, 2012).

Bone is a connective tissue associating a fibrous organic matrix essentially made of collagen and a mineral part, more or less porous, comparable to a poorly crystallized calcium phosphate apatite, ensuring the rigidity of the bone tissue. The bone is in perpetual remodeling under the action of osteoblast cells, responsible for its formation and mineralization and osteoclast cells, contributing to its resorption. This continual renewal mechanism confers to the bone self-healing properties (Thomas *et al.*, 2008). Nevertheless, in some critical situations due to trauma or diseases and resulting in significant bone loss, the natural remodeling process is not sufficient to ensure the total restoration of the damaged tissues and justifies the use of external input. The concept of replacing missing bone tissue has emerged for centuries with traces of orthopedic treatments found in Pre-Columbian and Egyptian civilizations (de Grado *et al.*, 2018).

The replacement by natural biological materials was thus firstly considered. Nowadays, these transplants come from the patient himself (autograft), from another patient (allograft), or from an animal (xenograft). The autogenous graft is often viewed by surgeons as the gold standard. The use of autografts is thus quite widespread in order to prevent the risk of pathologies transmission induced by foreign grafts. Nevertheless, several major drawbacks, as additional surgery, limited quantity, inappropriate shape, chronic pain and infection risks, lead hospital practitioners to consider other techniques. Consequently, the use of bone substitute engineered products has widely expanded in the last decades. An essential criterion for the substitute is the absence of cytotoxic effect for the organism. This characteristic is called biocompatibility and was defined in 1987 by Williams as “the ability of a material to perform with an appropriate host response in a specific application” (Williams, 1987). Scientists have then enriched the vocabulary of bone tissue engineering by involving other more specific notions as osseointegration, osteoconduction, osteoinduction, bioresorption, *etc.* In addition to natural origin materials, several families of synthetic materials can meet some of these relevant criteria and thus be considered for bone substitution: metals and metal alloys, ceramics and glasses, polymers and composites (Ratner *et al.*, 2013). Biomaterials for bone substitution were classified according to the different phenomena observed at the bone/material interface. Three generations were thus defined. The materials of the first generation can be qualified as biotolerant but bioinert. The second and third generations gather all the bioactive materials with a distinction between osteoconductive ones in case of second generation and osteoinductive ones for the third generation (Hench, 1991; Cao and Hench, 1996; Bongio *et al.*, 2010). In the case of critical bone defects, reconstruction often uses several categories of materials. Indeed, the defect filling is ensured by bioactive materials of second or even third generation, while the support of the host bone/substitute combination, during healing, is ensured by inert fixations made of first generation materials.

This review provides an overview of materials from natural and synthetic origin, specifically in the field of bioceramics and bioglasses, applied to bone substitution and the developmental multidisciplinary approaches currently considered to improve the integration and bioactivity of these bone implants. This document is divided into three sections corresponding respectively to the different tracks used by researchers and suppliers to influence the biological performance of the implants. These are the chemical composition of the materials, the physical shape of the implants and the functionalization of the biomaterials.

Material Composition

Natural Origin

Autografts

The specific properties of an ideal bone substitute are being biocompatible, bioresorbable, osteoconductive, osteoinductive, structurally similar to bone, porous, mechanically resistant, easy to use, safe, and cost-effective (de Grado *et al.*, 2018). Regarding these specifications, autologous graft or autograft is the only type of graft to meet them all and that's why it is still the gold standard for bone filling. Indeed, taken from an anatomical site and transplanted to another site within the same individuals, the autologous bone graft can integrate more quickly and completely in the host bone with a progressive resorption followed by a replacement by a new viable bone (Wang and Yeung, 2017a; Shin *et al.*, 2015). Moreover, autografts may retain some cell viability and are considered to promote bone healing mainly through osteogenesis and/or osteoconduction. In addition, no rejection problem or disease transmission is expected after implantation of autologous grafts (Shin *et al.*, 2015). This kind of graft can be harvested either from intraoral or extra-oral donor sites. Intraoral donor sites include edentulous ridges, extraction sockets, mandibular ramus, symphysis, maxillary tuberosity, *etc.* Popular sources of extra-oral donor sites are the tibia, iliac crest, and calvarium (Shin *et al.*, 2015).

There are different types of commonly used autologous grafting like cancellous, cortical or vascularized autograft then bone marrow aspirate and platelet-rich plasma (Roberts and Rosenbaum, 2012).

Generally, cancellous bone is the most commonly used form of autologous bone grafting. Its superior osteogenic potential is due to the presence of high concentrations of osteoblasts and osteocytes. In addition, its large trabecular surface area encourages revascularization and incorporation at the recipient site. Unlike cancellous bone, whose low density provides little mechanical support, cortical bone possesses excellent structural integrity. However, its dense, highly organized structure is a limit for the supply of osteoblasts, osteocytes and other cellular progenitors leading to limited osteogenic and osteoinductive properties. In vascularized grafts, the graft's osteocytes and other osteoprogenitor cells are preserved. This may increase the graft's osteogenic potential and prevent the initial loss of graft strength seen with non-vascularized cortical grafts. Harvesting of such a vascularized bone graft requires the preservation of its nutrients, metaphyseal and/or additional perforating vessels, such as arteries and veins, in neighboring vessels upon delivery to the recipient site. Although bone marrow aspirate, which is the spongy tissue inside some of human larger bones, are less commonly employed than cancellous or cortical grafts, it has been shown to be effective in the treatment of bone defects and nonunions in some cases. Obtained from bone marrow aspiration, it is injected as a viscous fluid at the defective site but don't provide any structural support. Finally, platelet-rich plasma (PRP) is an autologous suspension of platelets prepared from whole blood *via* double-centrifugation techniques. PRP is rich in several key growth factors due to its high concentrations of platelets. Growth factors are polypeptides that act locally as modulators of cellular activities and naturally occur within a healthy bone matrix or are expressed during fracture healing. The combination of synthetic bone substitutes with bone-active growth factors is promising to achieve an optimal bone healing. Currently, a few biological factors like bone morphogenetic proteins (BMPs), fibroblast growth factors (FGF), vascular endothelial growth factors (VEGF), parathyroid hormone (PTH) and platelet-rich plasma (PRP) have been studied and clinically tested. In PRP, platelets are activated with calcium chloride after their extraction from the patients' blood and can be applied to the site of injury. (Roberts and Rosenbaum, 2012; Shin *et al.*, 2015).

As mentioned above, only autograft currently meets all the properties of an ideal bone graft especially an osteoconductive matrix, osteogenic cells and osteoinductive proteins. The lack of immune response is also a major advantage of this technique. However, the drawbacks of the autograft related to the harvesting process, including donor site complication and pain, increased blood loss, increased operative time, potential for donor site infection and limited volume of material available have been too extensively reported (Roberts and Rosenbaum, 2012; Wang and Yeung, 2017a; de Grado *et al.*, 2018).

Allografts

Allogeneic bone grafting or allografts refer to bone taken from human corpses, treated sterile and transplanted to a recipient (Roberts and Rosenbaum, 2012). Given the limitation of autologous bone grafts, bone allograft is considered the best alternative to autografts and has been used effectively in many circumstances, especially for patients with low healing potential, non-union established and extended comminution after fractures (Wang and Yeung, 2017a).

Due to its possibility to be machined and customized, allograft is present in a variety of forms, including osteochondral, cortical, cancellous and highly processed bone derivatives such as demineralized bone matrix (DBM) (Roberts and Rosenbaum, 2012; Wang and Yeung, 2017a). This kind of graft can exhibit osteoconductive and sometimes osteoinductive potential depending on the preparation process. In most of the cases, allografts do not include viable cells and are therefore not osteogenic, except for bone marrow allograft transplant, which can be employed in fracture healing (Roberts and Rosenbaum, 2012). Finally, compared to autografts, allografts are found to be immunogenic and demonstrate a higher failure rate (Wang and Yeung, 2017a).

Allograft has become a popular alternative to autologous bone grafting due to the lack of morbidity at the donor site, the reduction in surgical time and the general success of the results (Roberts and Rosenbaum, 2012). Nevertheless, the major drawbacks of allografts are the risk of disease transmission and the high costs of such material. Indeed, a risk of disease transmission exists like, for example cases of HIV or hepatitis B and C transmissions have been reported. The transmission of any other kind of viruses is not to be excluded even if procedures have been significantly improved by the development of modern tissue banks and improvement in processing technology. (de Grado *et al.*, 2018; Wang and Yeung, 2017a; Roberts and Rosenbaum, 2012). In addition to ethical issues, high production costs have to be considered because allografts need to be treated and sterilized before to be stored and clinically used. This could represent a significant cost contrary to the absence of storage during a autogenous bone graft procedure (de Grado *et al.*, 2018).

Cancellous allografts

Mostly supplied in the form of cuboid blocks, cancellous allografts are the most common types of commercial allogeneic grafts. Due to the poor mechanical properties they confer and their relatively weak capacity to promote healing, spongy allografts are mainly applied in the increase of spinal fusion and the filling material for cavitory skeletal defects. Indeed, compared to autografts, they are a relatively poor promoter of healing due to their preparation process. A similar but slower sequence of events occurs in the process of incorporating allografts compared to autograft. Unlike incorporation of autologous cancellous graft, an inflammatory response from the local host results in the incorporation of cancellous allograft, leading to the production of an encapsulated layer of fibrous tissue around the graft. During this time, the allografts remain trapped and are never completely absorbed several years after the transplant (Roberts and Rosenbaum, 2012; Wang and Yeung, 2017a; Goldberg and Akhavan, 2005).

Cortical allografts

In addition to being readily available, cortical allografts provide rigid structural support and can be used in conjunction with multiple other fracture repair techniques. Like cortical autografts, they can be used to fill large defects and allow sometimes early weight bearing even before bony incorporation. Indeed, they can be placed in areas requiring immediate load-bearing resistance due to their resistance to compressive strength. For this reason, cortical allografts are a commonly employed in spine procedures and are also frequently used to provide stabilization to the femoral shaft in the setting of periprosthetic hip fractures (Roberts and Rosenbaum, 2012).

Usually, transplanted allografts are frozen or freeze-dried products free from marrow and blood because of immune responses and safety reasons. Like cancellous allograft, cortical allograft incorporation involves an initial inflammatory response and is also preceded by creeping substitution in a similar way than its autogenous counterpart. In general, the process is initiated by osteoclastic resorption and followed by the sporadic formation of new apposition bones by osteoconduction (Wang and Yeung, 2017a; Roberts and Rosenbaum, 2012; Goldberg and Akhavan, 2005).

Demineralized bone matrix (DBM)

Demineralized bone matrix (DBM) is a kind of highly processed allograft derivative with at least 40% of the mineral content of the bone matrix removed by acid treatment, while collagens, proteins and growth factors remain (Boyce *et al.*, 1999). Thus, it can be considered as an artificial allograft and is available in the form of lyophilized powder, crushed granules, chips, dough, gels or injection mixture of DBM with autologous bone marrow (Connolly, 1995).

DBM is a popular supplement to vertebral fusion procedures, nonunion of grafts and filling of bone defects. Its osteoinductive properties are greater than those of cancellous or cortical allografts. Indeed, the osteoinductive property of DBM is mainly determined by the remaining growth factors, which are directly correlated with preparation techniques. Techniques involving alcohol, acetic acid, lactic acid and nitric acid have been demonstrated to have a detrimental effect on osteoinductivity. That is why most of the commercially available DBM today is washed with hydrochloric acid. Concerning DBM osteoconductivity, it is conferred by providing a framework for cell populating and for generating new bone after the demineralization treatment. In addition, some modern DBM preparations are mixed with cortical and/or cancellous bone chips to provide additional osteoconductive properties. Like the autogenic graft, the incorporation of DBM starts with growth factors triggering a cascade of endochondral ossification and leading to new bone formation at the implantation site (Roberts and Rosenbaum, 2012; Goldberg and Akhavan, 2005; Wang and Yeung, 2017b).

No immunological rejection is present with DBM because the antigenic surface structure of the bone is destroyed during its acid demineralization. The use of DBM prevents donor site morbidity and comparable pain intensity has been shown after the surgical procedure compared to autograft procedures. Despite a suitable availability, demineralized bone matrix is more expensive than an iliac crest bone autograft procedure and its mechanical properties are quite low. Thereby, DBM is not currently used as a stand-alone bone substitute but preferentially for filling purposes (de Grado *et al.*, 2018; Campana *et al.*, 2014; Kinney *et al.*, 2010; Pieske *et al.*, 2009).

Xenografts

Another alternative to autograft could be the use of xenogenic bone or xenografts. Xenograft bone substitutes have their origin from a species other than human, such as bovine or porcine bone and corals which can be freeze dried or demineralized and deproteinized. They are usually only distributed as a calcified matrix after several treatments (de Grado *et al.*, 2018; Campana *et al.*, 2014; Wang and Yeung, 2017a).

Among xenograft materials, coral based xenografts have been approved to be used as bone substitutes in 1992 by the Food and Drug Administration (FDA), which is the national health product regulatory agency in the United States (de Grado *et al.*, 2018). Indeed, corals have interconnected pores and a skeleton quite similar to cortical and spongy bones. Madreporite and/or milleporite type of corals are harvested and treated to become “coral derived granules” (CDG) and other types of coralline xenografts. Coral-based substitutes are mainly calcium carbonate while natural human bone is made of hydroxyapatite (HA) along with calcium phosphate and carbonate. A large proportion of fluorides, useful in the context of grafting to promote bone development, can also be found in coralline materials. Further, the coral material can remain in its calcium carbonate state or either be transformed industrially into hydroxyapatite through a hydrothermal process. Its calcium carbonate form has the advantage of a better resorption of the graft by the natural bone while its transformation to hydroxyapatite yields to a non-resorbable xenograft. Coralline HA can be used as growth factors carrier, such as BMP (Bone Morphogenetic Proteins), TGF- β (Transforming Growth Factor-beta), or FGF (Fibroblast Growth Factor). It can be found in different aspects like granules or blocks and it is able to provide immediate support, rapid ingrowth and healing of cancellous bones. Despite its slow resorption, it does not induce adverse effects. In addition, coralline HA is osteoconductive, may show excellent bone binding capacity, avoids donor site morbidities and is unlikely to promote disease transmission or the risk of deep infections. The main problems of coralline hydroxyapatite are minimal remodeling due to high crystallinity coupled with its insoluble nature and the fact that osteoclasts cannot absorb it, so that these implants live in the implantation site throughout their life (de Grado *et al.*, 2018; Campana *et al.*, 2014; Wang and Yeung, 2017a; Roberts and Rosenbaum, 2012).

Even if xenografts present interesting advantages like the easy availability, the osteoconductivity, the good mechanical properties and low costs, the same limitations than allografts persist. Indeed, there is still a risk of immunogenicity problems and disease transmission concerning the porcine endogenous retrovirus (PERV) and the bovine spongiform encephalopathy (BSE).

Finally, patients beliefs can be a restriction on the acceptance and the use of this technique by the medical team (de Grado *et al.*, 2018; Campana *et al.*, 2014).

Synthetic Origin

In order to avoid all the limitations of the above-mentioned autografts, allografts and xenografts, in particular the severe shortage of natural bone grafts faced with an aging population, the use of synthetic bone substitutes is becoming more and more popular (de Grado *et al.*, 2018; Wang and Yeung, 2017a).

For the engineering of synthetic bone substitutes, the first input to be considered is the raw material. Currently, bioceramics, bioactive glass, polymers or combinations thereof are the most commonly available synthetic materials for bone substitutes (Wang and Yeung, 2017a; Roberts and Rosenbaum, 2012).

Bioceramics

1st generation: Inert bioceramics

The first objective in the research of ceramic materials for bone substitutes, starting in the 1950s, is to use inert materials which have no reaction with living tissues. This first generation is formed by inert ceramics with the most well-known examples, zirconia (ZrO_2 , zirconium dioxide) and alumina (Al_2O_3 , aluminum oxide) which are primarily used in the fabrication of femoral heads. However, these inert ceramics experiment foreign body reactions in a similar way to what happens with metallic and polymeric biomaterials. Therefore, even if they are biocompatible, they will give rise to a foreign body surrounding the implant by an acellular collagen capsule which will isolate it from the body. In this way, an inert ceramic does not form a bonding to bone and will never transform itself into bone (Vallet-regí, 2010; Hench, 1991). Yet, release of substances from zirconia and alumina implants to the surrounding tissue is very low and neither local nor systemic effects have been reported (Li and Hastings, 2016).

Oxide ceramics like alumina and zirconia exhibit superior mechanical properties, corrosion and wear resistance. Indeed, they are stable even in the most invasive industrial and biomedical environments. Their high strength, excellent corrosion and wear resistance and stability, non-toxicity and biocompatibility *in vivo* make them adequate candidates for load-bearing hard tissue replacements and fixation implants in dentistry and surgery. Alumina bioceramics are in the pure aluminum oxide form and their most established example of bone substitute application is the total hip endoprosthesis with a combination of metallic stem, ceramic ball and ultra-high molecule weight polyethylene (UHMWPE). On another side, zirconia bioceramics are partially stabilized by additional oxides like yttrium oxide, calcium oxide or magnesium oxide and are mostly used in hip ball and dental implants. Alumina and zirconia can also be both used for alveolar ridge reconstruction, maxillofacial reconstruction, as bone substitutes and in ophthalmology, knee prosthesis, bone screws as well as other applications as dental biomaterials, such as dental crown core, post, bracket and inlay (Li and Hastings, 2016).

Concerning mechanical properties of oxide bioceramics, alumina is mechanically weaker than zirconia although it is chemically more stable. Moreover, the phase changes in zirconia produce a unique ceramic material having much higher strength and higher fracture toughness compared with alumina and other ceramics. Indeed, as first discovered by Garvie *et al.* (1975), an increase of both strength and fracture toughness can be obtained by utilizing the zirconia tetragonal-monoclinic phase transformation induced by the presence of the stress field ahead of a crack. During this transformation, the variation in volume and the shear deformation developed in the reaction are recognized as opposing the opening of the crack and therefore acting to increase the resistance to crack propagation. As a consequence, zirconia resulting excellent mechanical properties allow to design implants with increased long-term clinical performance (Li and Hastings, 2016; Garvie *et al.*, 1975).

2nd generation: Bioactive bioceramics

Later in the advancement of ceramic research for bone applications, in the 1980s, the new trend became the manufacturing of ceramics implants that react with the environment and produce newly formed bone. The search for bioactive ceramics yielded to promising results with ceramics that can react with the physiological fluids forming biological-type apatite. Further, in the presence of living cells, this apatite can form new bone. Among these bioactive ceramics, calcium phosphate (CaP) and calcium sulfate are effective and well-known materials. These bioactive ceramics form the second generation of bioceramics. For medical applications, these materials are provided in several formats: powder, porous pieces, dense pieces, injectable mixtures and coatings. They have excellent features in terms of biocompatibility and bioactivity, but their mechanical properties are really poor (Hench, 1991; Vallet-regí, 2010; Wang and Yeung, 2017a).

Calcium phosphate

Calcium phosphate (CaP) is the common name of a family of minerals containing calcium cations (Ca^{2+}) together with orthophosphate (PO_4^{3-}), metaphosphate (PO_3^-), or pyrophosphate ($\text{P}_2\text{O}_7^{4-}$) anions, and sometimes hydrogen (H^+) or hydroxide (OH^-) ions. They are the principal form of calcium found in bovine milk and blood and the major inorganic constituent of bone and tooth enamel (Eliaz and Metoki, 2017). Calcium phosphate compounds used in bone grafting include monocalcium phosphate, dicalcium phosphate, tricalcium phosphate (both alpha- and beta- crystalline forms), hydroxyapatite and tetracalcium phosphate (Roberts and Rosenbaum, 2012). These synthetic materials can be processed in both dense and porous forms in bulk, as well as in the forms of powders, granules, cements/pastes, scaffolds or coatings as a function of the

biomedical applications. Common commercially available forms of CaP are porous implants, non-porous dense implants and granular particles with pores (Habraken *et al.*, 2016; Wang and Yeung, 2017a).

Most common CaP synthesis methods can be separated in different categories: dry methods, wet methods, high temperature processes or synthesis from biogenic sources (Sadat-Shojai *et al.*, 2013). Dry methods do not use a solvent, unlike wet methods, and can be performed in two main ways: solid-state synthesis and mechanochemical process. The main advantages of these methods are the possibility to produce highly crystalline CaP from relatively inexpensive raw materials. However, the large size of particles in the case of solid-state synthesis and the low phase purity in the case of mechanochemical process are major drawbacks (Sadat-Shojai *et al.*, 2013). Unlike dry methods, wet methods have conventionally been applied to the preparation of CaP particles having a nanosized structure with a regular morphology. Indeed, wet chemical methods have the advantages in precise control over the morphology and size of particles. Aqueous solutions of various sources for phosphate and calcium ions are employed and CaP crystals are normally produced by precipitation. Wet processes can be performed by a number of technical routes classified into six groups: conventional chemical precipitation, hydrolysis method, sol-gel method, hydrothermal method, emulsion method, and sonochemical method. Nevertheless, difficulties in controlling the crystallinity and phase purity of nanoparticles, some technical issues and time-consuming details make some wet procedures unsuitable for scaling up to produce large quantities of CaP (Sadat-Shojai *et al.*, 2013; Canillas *et al.*, 2017a,b). In order to have a better control on the phase purity, high-temperature processes can be used to avoid undesirable CaP phases while producing CaP with high crystallinity and good chemical homogeneity. Currently, two possible routes for CaP high-temperature synthesis are combustion method and pyrolysis process. Yet, the main disadvantages are a poor control over the processing variables and generation of the secondary aggregates (Sadat-Shojai *et al.*, 2013; Canillas *et al.*, 2017a,b). Finally, biogenic sources mainly bone waste, eggshells, exoskeleton of marine organisms, naturally derived biomolecules, and biomembranes can be employed to produce CaP. The extraction of biominerals from biowastes is an interesting process due to the economic and environmental benefits of waste recovery. In addition, some extracted ceramics present some superior characteristics like a better acceptance by the living organs, because of its physicochemical similarity to the human bone apatite. In a near future, this approach is expected to attract more attention, especially to overcome the current drawbacks. Indeed, some of these waste materials can be exclusively used to produce CaP blocks or particles of large size (Sadat-Shojai *et al.*, 2013).

Depending on the forms and requirements needed for CaP materials, different techniques can be used. Processing of ceramic pieces normally consist in two steps, the shaping and the following sintering. Most common shaping methods include: uniaxial compaction, isostatic pressing, granulation, slip casting, gel casting, freeze casting, atomization, polymer replication, extrusion, low pressure injection, slurry, dipping or thermal spraying. Also, the shaping of CaP can be realized during cooling and solidification of previously melted raw materials. The second step, sintering, is a processing step to consolidate the shaped forms. During the sintering of CaP, different processes take place. First water, carbonates and remaining volatile chemicals from synthesis are removed. Second, shrinkage occurs as a consequence of the removal of these gases while powders densify, and grain size increases. There are also some chemical changes and chemical decomposition depending the CaP species. Conventionally, sintering is carried out in electric furnaces with quite long thermal cycles. However, alternative sintering methods such as hot isostatic pressing, microwave, spark plasma sintering or rate-controlled sintering have been proposed in order to obtain improved mechanical properties, by minimizing grain growth and shrinkage during sintering (Canillas *et al.*, 2017a,b; Eliaz and Metoki, 2017).

Among the CaP family, hydroxyapatite and tricalcium phosphate are the most studied and used for biomedical applications due to their excellent properties allowing them to promote rapid bone formation on their surface and assure fast bone healing (Wang and Yeung, 2017a; de Grado *et al.*, 2018; Eliaz and Metoki, 2017; Habraken *et al.*, 2016).

Hydroxyapatite (HA)

Hydroxyapatite (HA) is one of the most studied CaP compounds and has the specific formula $(\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2)$. Its Ca/P ratio is 1.67 and it is part of the apatite family, which includes crystalline compounds with crystalline hexagonal lattice. Hydroxyapatite accounts for nearly 70% of the mineral content of teeth and bone but it is present in a substituted form. Indeed, pure, stoichiometric HA never occurs in biological systems. In fact, mineral species like carbonate, silicate, magnesium as well as other ions can replace hydroxyl or phosphate groups in the apatite structure (Campana *et al.*, 2014; de Grado *et al.*, 2018; Eliaz and Metoki, 2017; Wang and Yeung, 2017a).

Hydroxyapatite is recognized as a good bone graft material since it is a bioactive substance forming a strong chemical bond with host bone tissue. In addition to its bioactivity, HA is also osteoconductive, non-toxic, non-immunogenic and has similar mechanical properties compared to the cancellous bone. HA ceramic parts can be manufactured with a macroporosity and pore interconnectivity to allow the adhesion, proliferation, differentiation of osteoprogenitor cells, the revascularization and subsequently ingrowths of new bone after implantation (Campana *et al.*, 2014; de Grado *et al.*, 2018).

Because of its chemical similarity with the biological mineral in bone and teeth, HA is widely employed in different clinical uses from augmenting atrophic alveolar ridges to repairing long bone defects, non united bone fractures, middle ear prostheses, spinal fusions, and craniofacial repair. Moreover, hydroxyapatite has also been used in dental surgery, biomolecular and drug delivery, as well as for coating on orthopedic and dental implants (Eliaz and Metoki, 2017).

However, the major drawback of hydroxyapatite is its very low *in vivo* resorption. Its relatively high Ca/P ratio and its crystallinity delay its resorption rate leading to its retention at least up to 3 years after implantation. This could be an issue since the remaining hydroxyapatite grafts could compromise the intrinsic strength of the new-formed bone at the defect site. Indeed, it

has been shown that mechanical properties of HA grafts generally decrease by 30%–40% *in situ* after being implanted for several months (Wang and Yeung, 2017a; de Grado *et al.*, 2018; Campana *et al.*, 2014).

Tricalcium phosphate (TCP)

Tricalcium phosphate belongs to the whitlockite family characterized by the general formula $(\text{Ca,Mg})_3(\text{PO}_4)_2$. TCP can be found as three poly-morph phases: β , α and α' . Both α -TCP and β -TCP are used in clinics for bone repair and remodeling applications. Indeed, while β -TCP is mainly used for the manufacturing of biodegradable bioceramics shaped as dense or macro-porous granules and blocks, the more soluble and reactive α -TCP is mainly used as a fine powder in the preparation of calcium phosphate cements (Carrodegua and De Aza, 2011; Canillas *et al.*, 2017a,b; Wang and Yeung, 2017a; de Grado *et al.*, 2018).

Especially β -TCP has been widely studied since its discovery in 1920 and has largely been used as a bone substitute for more than 25 years, mainly for orthopedics and dentistry applications. It presents excellent properties like biocompatibility, osteoconductivity and bioresorption. Indeed, with its chemical formula of $\text{Ca}_3(\text{PO}_4)_2$ and a Ca/P ratio of 1.5, β -TCP is characterized by a better resorption *in vivo* compared to hydroxyapatite. Typically, β -TCP grafts are gradually resorbed by osteoclasts and replaced by remodeled bone in weeks after implantation. For this reason, TCP is one of the most effective materials for filling bone defects caused by trauma and benign tumors since it serves as a temporary support for bone healing. Moreover, the presence of a porous interconnected structure may accelerate the bone remodeling ability of β -TCP by facilitating the colonization of osteogenic cells and nutrients *via* an enhanced capillarity (de Grado *et al.*, 2018; Wang and Yeung, 2017a; Eliaz and Metoki, 2017).

Some current clinical uses of tricalcium phosphate are spine fusion, open-wedge tibial osteotomy, contained bone defects, hand surgery, oral/periodontal procedures and drug carriers. The use of β -TCP has shown really few complications like infection or nonunion. Nevertheless, this material presents some drawbacks like its unpredictable bioresorption and its poor mechanical properties. Indeed, β -TCP mechanical properties are still inferior to cancellous bone or bone allografts ones in most cases (de Grado *et al.*, 2018; Eliaz and Metoki, 2017; Wang and Yeung, 2017a; Canillas *et al.*, 2017a,b).

Biphasic calcium phosphate (BCP)

Since 1985, the term BCP describes bioceramics consisting of a mixture of HA and β -TCP phases. This kind of mixtures is widely used in commercial ceramic in order to combine the advantages of both calcium salts. Indeed, this association presents all the advantages of both components like osteoconductivity, biocompatibility, safety and promotion of bone formation. However, the main profit of BCP is the possibility to control the bioresorption. Of course, as mentioned above, the resorption of β -TCP is faster than the resorption of hydroxyapatite due to its smaller Ca/P ratio. Yet, HA presents better mechanical properties than β -TCP with average compressive resistances of 160 and 100 MPa, respectively. So, the combination of both allows, on one hand, a faster resorption and a higher bone ingrowth rate than using HA alone. On the other hand, it confers better mechanical properties and a more controlled resorption than β -TCP alone (de Grado *et al.*, 2018; Wang and Yeung, 2017a; Canillas *et al.*, 2017a,b).

BCP with different HA/ β -TCP ratios can be produced to adjust the dissolution rate and mechanical properties. Biphasic calcium phosphate can be useful as implant coatings or can be prepared in compact form or porous forms with interconnected macropores to mimic the cancellous bone structure. Some compositions are commercially available as bone graft or bone substitute biomaterials for orthopedic, maxillofacial and dental applications. Sometimes, they can be associated with bone marrow aspirate which then provides enhanced osteogenic properties. Despite the improvement of mechanical properties by the mixing of β -TCP and HA, the strength of BCP ceramics is still lower than cortical bone compression strength, which is between 150 and 200 MPa (de Grado *et al.*, 2018; Wang and Yeung, 2017a; Canillas *et al.*, 2017a,b).

Doped CaP

Some strategies have been considered in order to improve the mechanical and biological properties of synthetic calcium phosphate. One of them consists of doping calcium phosphate with different dopants. The first type of doping involves cationic substitution, where monovalent, bivalent and multivalent cations replace Ca^{2+} into the CaP lattice sites. The most well-known examples are Mg^{2+} , Sr^{2+} , Zn^{2+} or Ag^+ . A second type of doping implies the anionic substitution, where hydroxyl and/or phosphate sites are substituted by anionic species like F^- , Cl^- , OH^- , CO_3^{2-} or PO_4^{3-} . Usually present as traces, these ions can affect the lattice parameters, the crystallinity, the dissolution kinetics and other physical properties of CaP (Tite *et al.*, 2018; Adzila *et al.*, 2012; Boanini *et al.*, 2010).

These dopants are used for different reasons. First of all, doping of synthetic CaP can be useful to mimic the natural mineral bone composition which is an apatite characterized by small dimensions, low crystallinity and non-stoichiometric composition containing significant amount of CO_3^{2-} ions. Another role of dopant substitution is the possibility to increase the thermal stability of some CaP phases. The most famous example is the thermal stabilization of β -TCP. Indeed, there is a main difficulty concerning the sintering of β -TCP since it undergoes a phase transformation to α form around 1150°C. This phase transformation is accompanied by a sudden dilatometric expansion leading to mechanical stresses inducing cracks within the ceramic part. This phase transformation limits the mechanical reliability of TCP ceramics sintered above the transformation temperature. To avoid these difficulties, it has been shown that the addition of dopants like Mg^{2+} , Zn^{2+} and Sr^{2+} can stabilize the β -TCP phase and postpone its problematic allotropic transition to higher temperatures. Finally, ionic substitution serves also to optimize cell-material interactions of calcium phosphate and strengthening their mechanical properties. Indeed, the presence of minerals and traces of metal elements can aid bone growth and accelerate bone formation and resorption *in vivo*. Some ions have also been reported able to eliminate the bacterial presence around the CaP graft. Concerning the improvement of mechanical properties, the

substitution of calcium by other cations can increase the strength of some chemical bonds, shrink the lattice volume and strengthen the CaP mechanical behavior (Tite *et al.*, 2018; Boanini *et al.*, 2010; Adzila *et al.*, 2012; Champion, 2013).

CaP cements

Calcium phosphate cements (CPCs) were invented in 1986 by Brown and Chow in order to extend the adaptability and moldability of calcium phosphate bone substitutes. CaP cements consist of a calcium phosphate powder which is mixed with a liquid, usually an aqueous curing agent, to form a workable paste. CPCs can be easily injected to fill bone defects with various shapes and then solidified through an isothermal hardening reaction whose duration varies from 15 to 80 min depending on the formulation. After solidification and depending of its composition, the bioresorbable CPC can stay in the body for up to 2 years without resorption, to support bone healing. The possibility to fill complex bone cavity with such CaP pastes is the main advantage of CPC. Indeed, they allow avoiding gaps between the bone and the implant. In addition, some CPC compositions are injectable and absolutely useful in minimal invasive procedures such as vertebroplasty and kyphoplasty (de Grado *et al.*, 2018; Wang and Yeung, 2017a; Canillas *et al.*, 2017a,b).

According to the composition, properties of CPCs like their feasibility, setting reaction and biodegradation can change. Currently, two types of CPC can be distinguished. The first type is apatitic CPCs which are viscous with a relatively poor injectable ability. Nevertheless, the setting reaction can occur at the physiological pH value and the mechanical properties are slightly better than the second type of CaP cements, brushite CPCs. Indeed, the brushite CPCs demonstrate high but sometimes unpredictable degradability. However, they are feasible for injection and solidify quickly at a low pH value. In the same way as the other calcium phosphate substitutes, CPCs are biocompatible and osteoconductive but brittle leading occasionally to some complications (de Grado *et al.*, 2018; Wang and Yeung, 2017a).

Calcium sulfate

Another kind of commonly used synthetic material for bone substitutes is calcium sulfate. Also known as plaster of Paris, calcium sulfate (CaSO_4) is an osteoconductive and biodegradable ceramic applied in filling void defects since 1892. Indeed, it offers lots of advantages like being osteoconductive, non-allergenic, inexpensive and available in different forms. Its preparation consists of heating gypsum with a patented alpha-hemihydrate crystal structure and it can be manufactured into hard pellets or injectable viscous fluids that harden *in vivo* (de Grado *et al.*, 2018; Wang and Yeung, 2017a).

The main characteristic of calcium sulfate is its fast resorption, even faster than CaP phases like α / β -TCP. Indeed, it resorbs in 1–3 months *in vivo* after implantation and it creates porosity while stimulating bone ingrowth. This makes calcium sulfate the most rapidly absorbed synthetic bone substitute available. Its rapid resorption in addition to its lack of macroporous structure and weak mechanical properties make calcium sulfate an inappropriate material to support early functional rehabilitation. Actually, the resorption of calcium sulfate is faster than the deposition of new bone causing a non optimal fusion between the implant and the implantation site. For these reasons, calcium sulfate is more used to fill small bone defects with rigid internal fixation or as a support or a vehicle for local antibiotics or growth factors delivery. Indeed, calcium sulfate is a convincing choice of material for a combination with other synthetic bone substitutes because of its easy preparation and its low cost (de Grado *et al.*, 2018; Wang and Yeung, 2017a; Roberts and Rosenbaum, 2012).

Bioglasses

Bioactive glasses or bioglasses is a group of synthetic silicate-based ceramics. At the time of their discovery in 1970s, the Bioglass® composition was 45 wt% silicon dioxide (SiO_2), 24.5 wt% sodium oxide (Na_2O), 24.5 wt% calcium oxide (CaO) and 6 wt% phosphorus pentoxide (P_2O_5). Afterwards, some additives like potassium oxide (K_2O), magnesium oxide (MgO) and boric oxide (B_2O_3) were added to obtain a more stable composition (de Grado *et al.*, 2018; Wang and Yeung, 2017a).

Like the CaP and calcium sulfate ceramics, bioglasses are biocompatible, osteoconductive, do not induce any inflammatory response and often present a porous structure promoting resorption and bone ingrowths. Indeed, after implantation, a strong physical bonding takes place between bioglasses and host bones probably caused by the leaching and the accumulation of silicon and the formation of hydroxycarbonate apatite (HCA) layer on the surface of the glass. In fact, the surface of the bioglasses, subjected to an aqueous solution or to body fluids, starts to dissolve and transforms into a layer of gel rich in silica- $\text{CaO}/\text{P}_2\text{O}_5$ which then mineralizes into hydroxycarbonate apatite in a few hours. Hydroxycarbonate apatite is similar to bone mineral and interacts with collagen fibrils to create a bond with the host bone. This thin HCA film absorbs proteins, attracts osteo-progenitor cells and is partially replaced by bone through a creep substitution process. Bioglasses undergo relatively fast *in vivo* resorption and can be completely resorbed in six months. The greater the porosity, the faster the resorption following deposition of the new bone (Jones, 2013; de Grado *et al.*, 2018; Wang and Yeung, 2017a; Rahamana *et al.*, 2011).

Dissolution products of the glass, soluble silica and calcium ions, stimulate osteogenic cells to produce bone matrix and confer osteoinductive properties to bioglasses. Unlike CaP ceramics which are only osteoconductive because they support new bone growth, bioglasses are osteoconductive as well as osteoinductive. Indeed, they support new bone growth along the bone-implant interface as well as within the implant away from the bone-implant interface (Jones, 2013; Rahamana *et al.*, 2011).

Currently, there are several types of bioactive glass: the conventional silicates, such as Bioglass® 45S5, phosphate-based glasses and borate-based glasses. Phosphate glasses present very high solubility and it is possible to control this solubility by manipulating their composition. Borate glasses have really encouraging clinical results of healing of chronic wounds, they are easily to process and they show a faster degradation than silica-based bioglasses (Jones, 2013; de Grado *et al.*, 2018).

Different methods are available to prepare porous bioactive glass scaffolds. The conventional melt-quenching route consists in forming glass particles of a “melt-derived” glass into a construct with the desired architecture and geometry. After this shaping step, a mechanically reliable 3-D network with interconnected porosity is formed by the sintering of the structure where the particles are bond together. Other methods like sol-gel processing, electrospinning or processing of a viscous melt have also been used to prepare foldable scaffolds of bioactive glass (Jones, 2013; Rahamana *et al.*, 2011).

Concerning bioglasses biomedical applications, the original Bioglass 45S5 has been widely used to repair bone defects in the jaw and in orthopedics. However, bioglasses are quite brittle with low mechanical strength and decreased fracture resistance. For these reasons, bioactive glass porous scaffolds can only be used in sites where there is little load or only compressive load, for examples in the reconstruction of facial defects (de Grado *et al.*, 2018; Jones, 2013; Wang and Yeung, 2017a; Rahamana *et al.*, 2011).

Polymers

Compared to other bone substitute materials, polymers possess drastically different physical, mechanical and chemical properties. Polymers are macromolecules composed of covalently bonded monomers with a glass transition temperature that makes them quite flexible. Both natural and synthetic polymers can be used for bone repair applications (Campana *et al.*, 2014; Prakasam *et al.*, 2017).

Well-known natural polymers are starch, chitosan, derivatives of hyaluronic acid, collagen, fibrin gels and silk. The most used and important is collagen and can be found in bone. Indeed, bone is a composite mostly made of collagen and carbonate substituted hydroxyapatite arranged in a highly organized hierarchical structure which has a strong effect on the bone mechanical properties. Although collagen can be employed alone in some cases, it is mainly used in combination with other materials such as with bioceramics like hydroxyapatite. Actually, this kind of composite made with ceramic and collagen can combine benefits of both materials, especially in terms of mechanical properties. On one hand, the ductile properties of collagen help to increase the poor fracture toughness of bioceramics while the additions of ceramic particles to collagen give higher stability and resistance. In addition, such composites have been proved to be biocompatible and show better osteoconductive properties compared to the corresponding pure materials. Moreover, for surgical applications, the addition of collagen to a ceramic structure can provide shape control, spatial adaptation, increased particle and defect wall adhesion, and the capability to favor clot formation and stabilization. The main objective in the manufacturing of collagen-ceramic is to mimic the bone composition in order to reduce bacterial infections and risks of implant rejection. Some collagen-ceramic composites are already available in the market and suitable for spinal fusions. However, further studies are needed to assess the efficiency of such composites compared to other bone substitute materials (Campana *et al.*, 2014; Lawson and Czernuszka, 1998; de Grado *et al.*, 2018).

Concerning synthetic polymers for bone substitutes, they can be nondegradable or biodegradable depending on the composition. The most used nondegradable polymer is poly(methyl methacrylate) (PMMA) which is employed in orthopedics for 60 years. It is still currently a key material and one of the most enduring materials in orthopedic surgery due to its non-biodegradable and nonresorbable properties. PMMA is mainly used as cements for its high mechanical property and feasibility for handling. Actually, PMMA cements are of the most extended used materials for articular prosthesis fixation and vertebroplasty. Indeed, this polymer is rigid, biologically inert, relatively inexpensive, easy to obtain and minimally resorbed. This kind of cements can be prepared by mixing powdered methyl methacrylate polymer and liquid methyl methacrylate monomer, which polymerize during an exothermic reaction. This exothermic reaction can induce excessive heat and may potentially damage adjacent tissues. The main drawbacks of PMMA are its lack of bioactivity, its lack of replacement by new bone and its long-term susceptibility to infection or rejection (de Grado *et al.*, 2018; Campana *et al.*, 2014; Wang and Yeung, 2017a; Pryor *et al.*, 2009).

With the ability to be resorbed by the body, degradable polymers like poly lactic acid (PLA), poly glycolic acid (PGA), poly- β -hydroxybutyrate (PHB), poly lactic-co-glycolide (PLGA) and poly(ϵ -caprolactone) have the advantage of enhancing bone healing without remaining into the body. Depending on the type of polymer chain arrangement and its crystallinity/amorphous nature, the degradation rate can be modified. PCL, PGA and PLA are used for craniomaxillofacial fixation, sutures, interference screws, fixation plates and pins and for meniscus. However, these polymers lack mechanical strength and their degradation rate is not well controlled in addition to their tendency to induce inflammation reactions in the acidic medium. Moreover, they do not promote new bone growth and may rather inhibit it. An exception could be the PCL which is considered as a promising polymer since it is being used to enhance bone ingrowth and regeneration in the treatment of bone defects. Yet, its current slow degradation time limits its clinical use. Nevertheless, biodegradable polymers can be used as standalone devices, as extenders of autografts/allografts or as bioactive molecules or growth factors carriers. Current polymer-based bone substitutes exist in different forms but they are mainly studied in the field of tissue engineering for their manufacturing with macropores and micropores or also in the shape of thick membranes (de Grado *et al.*, 2018; Campana *et al.*, 2014; Wang and Yeung, 2017a; Sabir *et al.*, 2009; Prakasam *et al.*, 2017).

Composites

Finally, the different materials mentioned above can be associated and combined to form composites as explained with collagen and hydroxyapatite Section “Polymers”. A vast range of composite materials exists for bone repair applications. They differ by the components chosen and to the way they are assembled and processed. The main kinds of composites materials are organic/inorganic fiber composites, bioglass/polymer composites, hydrogel composites, polymer-polymer composites, multiphase ceramics and ceramic/polymer composites. Among them, biocomposites consisting of an inorganic dispersed phase in a polymer matrix are widely studied for their extremely promising properties as bone substitutes. The selection of components obviously

Fig. 1 The most used bone graft substitutes forms: (a) cements/pastes, (b) granules and (c) porous blocks/scaffolds; (a) and (b); (c). Reproduced from (a) and (b) Bohner, M., 2010. Resorbable biomaterials as bone graft substitutes. *Materials Today* 13 (1–2), 24–30. [https://doi.org/10.1016/S1369-7021\(10\)70014-6](https://doi.org/10.1016/S1369-7021(10)70014-6). (c) Miranda, P., *et al.*, 2006. Sintering and robocasting of β -tricalcium phosphate scaffolds for orthopaedic applications. *Acta Biomaterialia* 2, 457–466.

depends on the intended application, especially if the bone substitute is used or not in load-bearing areas or if it must be resorbable or not. Nevertheless, there is a main objective in biocomposites fabrication which consists in the reinforcement of a relatively low-modulus polymer with a high-modulus, high-strength reinforcing inorganic material. It is performed by using the plastic flow of the polymeric material under stress to transfer the load to the inorganic phase. In this way, a composite with a higher strength and modulus than the polymer alone and better toughness and process ability than the pure inorganic material can be produced. Biocomposites properties depend on the relative volume fraction of each of the phases and the way they are processed. The most commonly used polymers in combination with inorganic materials are chitosan, silk, gelatin, alginate, saturated poly- α -hydroxy esters, including PLA and PGA, their copolymer PLGA and PCL. These polymers can be mixed with inorganic powders or scaffolds like CaP, calcium sulfate or bioglasses. Due to their porosity and cell adhesion ability, biomaterial composites present a promising role in drug delivery. In addition, the manufacturing of inorganic/polymer composites also allows to mimic the bone structure and might receive higher demand in future for this reason (Grøndahl *et al.*, 2017; de Grado *et al.*, 2018; Bongio *et al.*, 2010; Kashirina *et al.*, 2019).

Finally, another type of composite is starting to get attention: the combination of synthetic materials with xenografts called xenohybrid. Indeed, it is becoming interesting in research as well as in industrial and clinical practices. This kind of composite presents high similarity with human cancellous bone and possesses higher bioactivity. Moreover, there is the possibility to tailor the degradation rate of the material and to incorporate active biomolecules. Although some studies pretend that this combination provides enhanced clinical performance, there is a need of more clinical data to further develop the properties of such materials. The major issue with the use of xenografts remains the alteration of both mechanical and biological performances through the cleaning and sterilization process (Haugen *et al.*, 2020; Ferracini *et al.*, 2019).

Comparison Natural Synthetic

Natural materials such as autograft, allograft, xenograft, demineralized bone matrix or natural polymers have been used beside synthetic materials like ceramics, bioglasses or polymers in bone repair applications. Although synthetic materials possess regenerative effects and are highly useful to solve the natural bone substitutes limitations, their lack of osteoinductive properties is a major issue. Indeed, most bone graft substitutes, especially synthetic ceramics and cements, do not possess any osteoinductive property. In fact, their ability of bone healing essentially comes from their osteoconductive properties. Yet, when the ideal implant site environment is disturbed, the absence of osteoinduction and the presence of bone growth factors can lead to delayed union or non-union. Actually, it has been proven that the presence of osteoinductive factors at the site of bone injury during bone healing is of great importance. For this reason, more and more researches focus on direct application of bone-active growth factors or combine them with synthetic biomaterials in order to achieve a maximal osteogenic effect. One of the most promising approaches is the incorporation of such active biomolecules into manufactured porous scaffolds to combine osteoconductivity and resorbability. These researches lead to the development of a new bone substitute's generation. This point is developed in the Section "Materials Functionalization and Drug Delivery Systems" (Wang and Yeung, 2017b; Schallenger *et al.*, 2014; Giannoudis *et al.*, 2007; Giannoudis *et al.*, 2008; Sheikh *et al.*, 2019).

Unlike synthetic materials, some human-derived bone substitutes like demineralized bone matrix (DBM) can possess osteoinductive properties and exhibit superior bone regeneration ability. In the case of DBM, it is due to the presence of native growth factors preserved and exposed through the demineralization process. However, the increasing demand of bone repair materials and the as-mentioned limitations of human-derived materials create a need to continue the development of new biomaterials or the improvement of known bone substitutes. Currently, autologous bone graft would be still the best choice for many bone repair applications but the relatively high donor morbidity and the limited amount which can be harvested are major issues. Allografts can avoid these limitations even if they present very variable osteoinductive properties and a risk of diseases transmission. Accordingly, future researches will be more focused on synthetic bone grafts especially for the optimization of grafts

stability, handling and biological properties (Zimmermann and Moghaddam, 2011). In addition to the material composition, one of the main challenges is the designing and the manufacturing of bone substitutes with favorable shapes, architectures and porosity for proper bone regeneration and vascularization. Indeed, biological properties and implant integration do not only depend on material composition but also on implant physical form (Schallenger *et al.*, 2014; Sheikh *et al.*, 2019; Wang and Yeung, 2017a).

Implants Physical Shape

The bone substitute materials may take a variety of forms, including pellets, granules, wedges, blocks/scaffolds, cements/pastes, putties, membranes and disks. The choice of the formulation depends of the application, the type of bone defect, the site and the geometry of the implantation site, the clinicians' preferences or the availability of the material. The as-mentioned types of formulations can be used as bone filler to assist and support the healing of bone defects too large to spontaneously heal. Actually, the most used bone graft substitutes are in the form of granules, cements/pastes or porous blocks/scaffolds (Bohner, 2010, 2014) (Fig. 1).

Granules

In the form angular or spherical particles, this type of bone substitute shape is the most used mainly due to its low cost, easy manufacturing and its quite fast bone ingrowths. The main advantage of granules is their ability to fill any defect form especially widely open defects where they can migrate during and after surgery. An optimal filling can be achieved by adjusting the granules characteristics like their morphology, shape, porosity, microstructure and size. Typically, irregular morphologies can cause undesirable *in vivo* inflammatory reactions leading to slower bone growth. For this reason, smooth geometries are preferred are superior. Even if spherical particles present a better flowability than angular granules to fill even small effects, they present high packing densities. This can limit the size of the space between the granules, so that bone growth is reduced as well as resorption due to smaller porosities and a larger amount of material. Thus, most of the current commercial products are angular with a size varying between 0.1 and 5 mm. This range of size is a compromise for an easy insertion in bone defects and a relatively simple handling of the granules during the surgery.

Bone filler granules can be produced by various techniques, depending on the material composition. Some of them are the crushing of blocks, hydrothermal conversion of natural corals, dripping, drip casting, gel casting and stirring mixtures of immiscible liquids. Block crushing can form granules of irregular shapes and sizes, which requires additional sieving and grinding procedures to obtain appropriate sizes and a more regular shape. Contrariwise, granules made by dripping, drip casting, gel casting and stirring mixtures of immiscible liquids present adequate spherical or near-spherical shapes.

Concerning the application of granules, small ones (< 1 mm) are preferably used in dental products while larger ones (> 1 mm) are more useful in orthopedics (Bohner, 2010, 2014; Hsu *et al.*, 2007).

Pastes/Cements/Putties

Pastes/cements and putties are the most suitable materials for the filling of closed defects since they can be directly injected with minimally invasive techniques. They can avoid the issues linked with the use of granules such as difficult handling, time-consuming filling and falling granules outside the defect. Indeed, injectable and/or moldable bone substitute formulations have been developed with the most used approaches consisting of mixing a polymer matrix with ceramic powders or granules. Two types of formulations can be distinguished as a function of hardening or non hardening properties. Typically, non hardening injectable pastes are called putties while pastes that harden are considered to be cements.

Most of the time, cements hardening after implantation by a setting reaction provide a better mechanical stability than putties by the physical entanglement of the materials. However, putties are characterized by a higher handling compared to hardening pastes (Bohner, 2010, 2014).

Cements

Among the different cement compositions, polymer- and mineral-based cements are the most famous. Concerning polymer-based cements, PMMA is widely used to anchor joint replacement prosthesis and to augment bone even if it presents some drawbacks. Indeed, this material is not resorbable and presents a toxicity leading to hypotension as well as a high exothermicity causing bone and tissue necrosis. Currently, alternative polymeric compositions and improvements to PMMA cements are studied to overcome these problems (Bohner, 2010, 2014).

Mineral-based cements mainly consist of ceramic-based cements composed of calcium sulfate, calcium silicate and/or calcium phosphate. Nowadays, almost 50 compositions are available by mixing the different materials. In order to obtain adequate injectable cements, different parameters such as the setting time, the setting rate, the injectability and the cohesion have to be optimized. Typically, the setting time should be close to 10 min while the setting rate should allow the end of the setting reaction shortly after the setting time. Moreover, cements must present the ability to be injected without a solid-liquid phase separation

Fig. 2 The main scaffold manufacturing techniques for biomaterials.

(injectability) and to keep its physical integrity during setting (cohesion). The hardening of such ceramic-based cements starts first with the dissolution of the reagent in the aqueous phase and second in the nucleation and growth of crystals. During this process, a large excess of water is often employed leading to highly porous cements with a pore size depending of the entangled crystals. Usually, these cements only contain micropores due to the micrometer-sized crystals. The absence of macropores can slow down the blood vessel and tissue ingrowths at the implantation site because it is only possible after the cement resorption. The entanglement of crystals after the hardening reaction lead to a quite high stability under compression but ceramic-based cements are brittle and weak, especially under tension and shear (Bohner, 2010; Habraken *et al.*, 2016; Bohner, 2014).

Putties

Most putties are prepared by mixing a polymer matrix and ceramic powders or granules. The polymer phase serves as a glue material for the solid particles. There are different examples in the literature like a mix of β -TCP granules with a sodium alginate solution or chitosan used to bond hydroxyapatite particles. Pure organic compositions also exist with, for example, PMMA and demineralized bone used alone to act as sealant in case of bleeding in bone. On the other hand, pure mineral compositions include, similarly to cements, hydraulic cements such as calcium sulfate and calcium phosphate cements. Some developments have been carried out to obtain putties made of nano- or micro-sized calcium phosphate particles and water. The absence of hardening reactions in putties allow them to be used in closed as well in open bone defects (Bohner, 2010, 2014).

Blocks/Scaffolds

Probably the most presently studied type of bone substitute formulation; blocks/scaffolds are generally used to fill large bone defects or defects with very well-defined geometries. Compared to other bone graft formulations, blocks/scaffolds offer different advantages. Although granules usually have better bone ingrowths, scaffolds present a higher mechanical stability and an easier handling than a pile of granules. Moreover, the well-defined geometry of scaffolds can avoid issues linked with possible uncontrollable extrusions of cements/putties. Indeed, in some cases, pastes can be extruded beyond the bone defects boundaries leading to their no-dissolution or to the damaging of surrounding tissues (Bohner, 2014).

Scaffolds can be used alone as acellular systems or combined with active molecules as vehicles for cells and/or drugs, as a function of the area and the severity of the bone defect. Scaffolds are commonly used alone in trauma, spine fusion markets or in dentistry. Indeed, wedges are often applied in knee osteotomy while cages are used for inter-vertebral body fusion. On another side, combinations of scaffolds with active molecules and/or stem cells are mainly employed in orthobiologics, typically substances used to help injuries to heal more quickly. These combinations can improve the bone implant integration and the promotion of bone formation. Currently, two great fields of applications are studied where the use of scaffolds could be beneficial. The first one, personalized medicine, requires personalized fabrication of synthetic implants and the second one, bone tissue engineering, needs to produce 3D scaffolds with complex tailored architecture (Champion *et al.*, 2017; Ho-shui-ling *et al.*, 2019).

In general, blocks/scaffolds are highly porous in order to provide fast bone ingrowth and rapid integration of the graft. Indeed, a scaffold is typically defined as an artificial structure used to support three-dimensional tissue formation where new cells can migrate and new vessels can form. An ideal bone scaffold should allow or improve cell viability, attachment, proliferation and homing, osteogenic differentiation, vascularization, host integration and, where necessary, load bearing. Moreover, it is vital to produce scaffolds quite similar to the natural environment, with multi-functional properties and efficient in terms of cost and

Sol – gel based materials for biomedical applications. *Progress in Materials Science* 77, 1–79.

clinical use. Indeed, implants should enable easy handling during surgeries with minimal preparatory procedures allowing industrial sterilization and reproducibility at lower cost.

Optimizations of scaffolds characteristics are so needed to meet these ideal requirements. Among them, bone substitutes architecture, including geometry and porosity, particularly draws the attention of researchers. It has been proven that scaffolds architecture and micro-architecture are of critical importance for bone regeneration. Typically, scaffolds should have distributed, interconnected pores and display a high porosity in order to ensure cell penetration, vascular ingrowth and nutrient diffusion, as well as waste products elimination. In addition, the mean pore size must be controlled to ensure proper cell colonization. Although the critical pore size range can vary as a function of cell and tissue type, a pore size comprised between 200 and 500 μm is considered optimal for bone regeneration and vascularization. Sometimes, pore sizes superior to 300 μm are recommended in order to enhance bone formation and the formation of capillaries (Roseti *et al.*, 2017; Bohner, 2014; Alaribe *et al.*, 2016).

Scaffolds manufacturing

Different technologies exist to manufacture porous scaffolds and they can be classified in to main categories: conventional and Additive Manufacturing (AM) techniques (Fig. 2).

Conventional techniques

Typically, in conventional manufacturing, scaffolds are produced by subtractive methods where an initial block is modified and shaped to the desired final form. Conventional technologies include solvent casting and particle leaching, freeze-drying, thermally induced phase separation, gas foaming, powder-forming, sol-gel, and electrospinning (Turnbull *et al.*, 2018; Roseti *et al.*, 2017; Thavornyutikarn *et al.*, 2014).

Solvent-casting and particle leaching

First, solvent-casting and particle leaching consist in the dissolution of a polymer solution in a solvent with uniformly distributed salt particles of a specific size (**Fig. 3(a)**). After evaporation of the solvent, it remains a salt particles-embedded matrix, which is then immersed in water. The contact with water leads to the leaching out of the salt and this allows producing a highly porous structure. This process presents different advantages like an ease to perform, low equipment costs while producing high scaffold porosity with the possibility to tune pore size. Nevertheless, the scaffold shapes that can be produced are quite simple and limited to sheets and tubes. Finally, some residual solvent can stay inside the structure leading to some harmful effects on biological species (Turnbull *et al.*, 2018; Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014).

Freeze-drying

Another widely used process in scaffold manufacturing is the freeze-drying process or lyophilization. In a similar way than solvent-casting, a synthetic polymer is dissolved into a suitable solvent before being frozen and solidified (**Fig. 3(d)**). After, the solvent is evaporated *via* sublimation producing a dry scaffold with an interconnected porous structure. The main benefit of freeze-drying is the low used temperatures allowing the incorporation of biological factors sensitive to high temperatures. Even if the pore size is simple to control, it usually leads to the production of irregular small size pores. Besides, this technique involves quite long process durations, high-energy consumption and the use of cytotoxic solvents (Turnbull *et al.*, 2018; Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014).

Thermally induced phase separation (TIPS)

Low temperatures are also applied in the Thermally Induced Phase Separation (TIPS) process. In this technique, a polymer solution is quenched and goes through a liquid-liquid phase separation to form a polymer-rich phase and phase poor in polymer (**Fig. 3(e)**). After solidification of the first one, the polymer poor phase is removed, leaving a very porous nanometric fiber network. As for the freeze-drying process, low temperatures involved in the TIPS are a plus for the possible incorporation of bioactive molecules (Turnbull *et al.*, 2018; Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014).

Gas foaming

In order to limit or avoid the use of organic solvents possibly cytotoxic, the gas foaming technique employs relatively inert gas-foaming agents like carbon dioxide or nitrogen (**Fig. 3(c)**). These agents are useful to produce sponge-like structures with an average pore size in the range of 30–700 μm and porosity up to 85%. Typically, molded biodegradable polymers are pressurized until saturation with water or fluoroform to introduce many bubbles into the polymer. Indeed, these bubbles are responsible for sponge-like structure obtained at the end of the process. In contrary to freeze-drying and TIPS, gas foaming includes the use of high temperatures during compression molding. Moreover, this technique usually leads to close, non-interconnected porous structures as well as nonporous skin layer at the scaffold surface (Turnbull *et al.*, 2018; Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014).

Powder-forming

The most well-known process to manufacture porous ceramic scaffolds is the powder-forming. In powder-forming processes, ceramic particles are put in suspensions with water or ethanol forming a slurry (**Fig. 3(f)**). This slurry is then used to produce green bodies by different ways. Dry or wet processes are available depending of the manufacturing conditions. Among them, the replication technique is particularly suitable to produce scaffolds with controlled shape and porosity. Commonly, it consists in the dispersion of ceramic slurry within a template, usually polymer foam with the desired macrostructure. Further, the drying of the solvent and the thermal decomposition of the template lead to the green body. Finally, the densification of the green part allows obtaining a scaffold with controllable pore size, high porosity and interconnectivity (Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014; Canillas *et al.*, 2017a,b).

Sol-gel

In addition to the as-mentioned processes, sol-gel technique can also be used to create ceramic or glass materials in the form of ultra-fine or spherical shaped powders, thin-film coatings, ceramic fibers, microporous inorganic membranes, monolithic parts and highly porous aerogels. The inorganic polymerization of metal alkoxides is employed in this process (**Fig. 3(g)**). Typically, the first step is the formation of a sol by the addition of a surfactant to the solid loading. This step is then followed by condensation and gelation reactions to form the gel. The sol-gel process is highly useful for the obtaining of scaffolds with controlled shape with a high purity at quite low temperatures. However, the major issue with scaffolds made by the sol-gel process is the low mechanical strength in most cases (Mahony and Jones, 2008; Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014).

Electrospinning

Finally, the electrospinning technique can be used to create nanofibrous architectures by the assembling of fine fibers (**Fig. 3(b)**). Indeed, by means of electrical charges and a syringe pump, it is possible to draw fibers up to the nanometer scale and use a collector to build structures. Actually, a polymer solution, loaded or not with particles (ceramic or bioglass for example), is placed into a container with a millimeter size nozzle and subjected to electric field. The generated electric field provokes the ejection of a charged liquid jet that is then elongated, projected and deposited on the collector. After evaporation of the solvent, ultra-thin fibers remain on the collector forming nanofibrous architecture with high surface area to volume ratios. This characteristic can help to

functionalize the fibers with different bioactive species. The use of organic solvents is a major disadvantage of electrospinning with the possibility of residual cytotoxic traces (Demir *et al.*, 2002; Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014).

The main challenge in the manufacturing of porous scaffolds by conventional technologies is the control of the shapes, geometries and internal architecture of produced parts. Most of conventional techniques cannot produce fully continuous interconnectivity and uniform pore morphology within a scaffold. Moreover, the lack of reproducibility inherent to some manual-based processes is a drawback to control scaffolds parameters like the pore size, pore geometry and spatial distribution. In addition, most conventional fabrication methods are using toxic organics as solvent or porogens and their residues in the scaffold can lead to severe inflammatory responses. To counter these limits, Additive Manufacturing methods have been developed and their use is increasing within the medical field. Indeed, AM techniques allow a more punctual and accurate control of porosity, pore size and, globally, of internal architecture. Therefore, biomaterials parts with reproducible properties can be produced and a better imitation of the natural bone tissue structure can be achieved. The main objective is to produce porous scaffolds with appropriate controlled pore size and high interconnectivity to promote cell penetration, tissue ingrowth, nutrients delivery and rapid vascular invasion while providing a proper mechanical integrity and degradation (Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014; Chartier *et al.*, 2015).

Additive manufacturing

Rapid prototyping, additive manufacturing, solid free form fabrication or 3D printing is defined by ASTM F2792-12a as the process of joining materials to make objects from 3D model data, usually layer upon layer, as opposed to subtractive manufacturing methodologies (Zocca *et al.*, 2015).

Different technologies are grouped under this term like Stereolithography (SLA), Fused Deposition Modeling (FDM), Selective Laser Sintering/Melting (SLS/SLM), 3D Printing (3DP) and Bioprinting. In all these processes, an object is created from a virtual model by adding material layer by layer. Among the AM techniques, liquid-, paste-, and powder-based processes can be distinguished (Turnbull *et al.*, 2018; Roseti *et al.*, 2017; Thavorniyutikarn *et al.*, 2014; Zocca *et al.*, 2015).

Stereolithography

The first invented Additive Manufacturing technique is the stereolithography, or SLA for Stereo-Lithography Apparatus, by which a solid object is formed by successively print thin layers of an ultraviolet (UV) curable material one on top of each other (Fig. 4(c)). Typically, a SLA machine consists of a tank of photo-sensitive liquid resin, a moveable built platform, an UV light source and a dynamic mirror system. Two types of stereo-lithography setups exist at the moment: the bottom-up and the top-down approaches. The main difference between the two processes is the position of the light source with respect to the resin tank. The light source is placed above the tank in the bottom-up process while the light comes from under the tank in the top-down approach. Moreover, there are two different types of light source. The classic light source is a UV laser beam scanning the resin bed to produce the final part. The more recent UV source is a DLP (Digital light projection) device where a digital mirror device (DMD) is made of up to several millions of mirrors that can be independently switched on or off. The SLA process can fabricate 3D scaffolds from polymers, bioceramics and composites. Indeed, biodegradable polymers such as poly(propylene fumarate) (PPF), photo-cross-linkable PCL, PDLA, vinyl esters and photocrosslinkable poly(ester anhydride) are successfully printed with this technique. In addition to the fabrication of hydrogel polymer scaffolds, SLA is also used to build a ceramic network using a photo-sensitive polymer as a binder. For this purpose, a liquid photosensitive resin is filled with ceramic particles with a solid content in the range of 20–50 vol percentages. The addition of a solid loading can lead to high viscosities introducing some difficulties to the process. After printing, debinding and sintering steps are needed to obtain ceramic-based scaffolds.

The main benefits of the stereolithography process are the freedom of designing structures, the ability to build parts of various sizes and a good surface finish. The spatial resolution is usually approximately 50 μm which is a very high accuracy and resolution compared to other Additive Manufacturing processes. SLA is suitable to create well-defined scaffolds with controlled interconnected porosity. However, there are still some limitations related to the use of photo-sensitive material and the debinding step usually highly time-consuming. The shrinkage of the polymer during the polymerization process can also alter the final shape of the printed part. A major issue is the possible cytotoxicity caused by photo-sensitive resins employed in the medical field. To counter these problems, more and more researches are focused on the development of alternative resins with a better debinding behavior and that possess a better biocompatibility *in vivo* (Roseti *et al.*, 2017; Thavornnyutikarn *et al.*, 2014; Zocca *et al.*, 2015; Melchels *et al.*, 2010).

Fused deposition modeling

Probably the most-well known additive manufacturing technique, the Fused Deposition Modeling (FDM) process uses molten thermoplastic materials to print desired shapes. In this process, the material is extruded from a nozzle and deposited onto a base platform following the 3D model (Fig. 4(d)). After the deposition of a layer, the platform or the nozzle moves to print other layers until the obtaining of the final object. This technique is quite useful to manufacture 3D scaffolds with controllable pore size and porosity by playing with the parameters like the material deposition amount, the spacing between the extruded filaments and the height interval. The FDM process is able to print scaffolds with a wide range of materials from polymers to ceramics and composites. Among polymers, PCL, PLA, PLGA and poly(butylene terephthalate) (PBT) are easily printed with this technique. Concerning the manufacturing of bioceramic scaffolds, there are two ways to use FDM to produce porous parts. The first method is called the fused deposition of ceramics (FDC) and uses a filament made of a thermoplastic polymer, a ceramic powder and a binder. After the printing, the 3D green ceramic part is debinded to remove the thermoplastic polymer as well as the binder and the part is densified by sintering. The other way to manufacture ceramic scaffolds with FDM is an indirect method called the lost mold technique. It uses an FDM machine to produce polymer molds with a negative structure of the intended network. After the mold printing, a ceramic slurry is cast into the mold and solidifies. The obtained object is then heated to remove the organics after the final sintering process to consolidate the ceramic network.

In the same way as ceramics, composite scaffolds combining polymers with bioglasses and ceramics can also be manufactured by the FDM process. The most studied compositions are PCL/HA, PCL/TCP and PCL with S53P4 bioactive glasses. Due to its low cost, the absence of organic solvent, the ability to form a fully interconnected porous 3D architecture and the ease of the process, especially the absence of object cleaning after printing, the FDM technique is an ideal way to produce biocompatible scaffolds. Indeed, it allows a flexible fabrication of interconnected porous scaffolds with the possibility to introduce compositional or morphological variation across the printed parts. Although FDM is highly reproducible, there are some limitations linked with the effect of high temperatures on raw material. Unlike SLA, its resolution is quite low because of the limited extruded filament diameter. Finally, the raw material selection is limited due to their shaping in the form of filaments with specific size. Preformed fibers need to have consistent size and properties to feed through the rollers and nozzle during printing. In order to overcome FDM issues, different processes derived from FDM have been optimized to improve the printing of porous scaffolds. These techniques include multi-head deposition system (MHDS), low-temperature deposition manufacturing (LDM), precision extruding deposition (PED), pressure-assisted microsyringe (PAM), robocasting and 3DBioplotter® system. (Roseti *et al.*, 2017; Thavornnyutikarn *et al.*, 2014).

Selective laser sintering/melting

The Selective Laser Sintering/Melting or SLS/SLM process is a powder-based technology and consists in binding together powder particles in thin layers with a high-power laser (Fig. 4(b)). Typically, the laser beam is able to fuse selected regions of the powder bed onto a surface forming a material layer. Then next layers of the material are deposited on the top of the bed by a roller and the process is repeated until the part is completed. In this process, the particle size and shape of the feedstock powder are major

parameters because they influence powder flowability and the final scaffold product. Due to low compaction forces present in the powder after the sintering process, printed structures have an internally porous structure suitable for a bone scaffolds. Therefore, SLS has been used polymers, metals and ceramics to produce tissue-engineered parts. Polymers PCL and poly-3-hydroxybutyrate (P3HB) have been successfully printed by SLS while manufacturing bioceramics directly present some difficulties. Indeed, the fast heating and cooling rates associated with the high-energy laser are not optimal to shape ceramic powders. Concerning composites, the most studied compositions are PCL/HA, PCL/TCP and poly(hydroxybutyrate-co-hydroxyvalerate) (PHBV)/TCP. In SLS, it is a challenge to find the optimal combination of the process parameters like powder composition, particle size, laser power, powder bed temperature, scan speed, scan spacing, and part orientation. Indeed, all of them influence the mechanical properties of the final printed scaffold.

The main advantage of SLS is the fact there is no need of additional supporting structures for the model during printing because unprocessed powders serve as a support. Moreover, this process does not use organic solvents or any toxic chemicals. Nevertheless, the relatively high laser temperatures and the heat transfer reactions induce some limitations. First, the heat can be harmful for polymers with possible degradation during the process. The direct laser sintering of ceramics is complicated by their poor resistance to thermal shock and the short interaction time between laser and powder limits the densification. For the production of complex-shaped prototypes or large prototypes by SLS processing, it is quite time-consuming. In addition, the powder trapped inside the small holes and pores can be sometimes impossible to remove. This can lead to the blocking of cellular ingrowth and to inflammatory reactions if the part is used as an implant. Finally, similar to SLA, the shape and size of the final printed part can be different from the 3D model due to shrinkage during the printing process (Roseti *et al.*, 2017; Thavornyutikarn *et al.*, 2014; Zocca *et al.*, 2015).

3D printing

The 3D printing or 3DP is an ink-jet printing technique based on the selective spraying of a liquid binder onto the layer of the powder bed. The binder merges particles together to form a solid layer (Fig. 4(e)). After the printing of a layer, the powder bed is lowered to spread a new powder layer with a roller and the process can continue until the formation of the final object. The printed parts are embedded inside not fused powders which need to be removed to reveal the final object. This process is suitable to create complex 3D scaffolds by using a broad variety of materials, including polymer, hydrogels, ceramics and composites. PLGA scaffolds were created by this technique as well as hydrogels parts made of PEG/collagen/PDL, PEO/PCL and starch/cellulose. In fact, 3D printing is the only solid-phase AM technique able to manufacture hydrogel scaffolds. However, due to their lack of mechanical strength, a post-treatment step involving infiltration and monomers crosslinking is necessary to produce stable pieces. In the same way as the SLS technique, ceramic-based scaffolds can be manufactured with 3DP systems even if a heat treatment is required to obtain higher densities in the final parts. The most tested bioceramic powders are hydroxyapatite and β -TCP. Bioglass powders and polymer/ceramic composites are also widely studied like PLGA/TCP and PCL/TCP combinations.

The 3D printing process presents several advantages like cheap raw materials, high build speeds and the absence of additional support structure similar to SLS. Moreover, unlike SLS, 3DP does not require the use of heat making possible the incorporation of biologically active molecules or thermosensitive compounds. Despite these benefits, the limited resolution and accuracy of this technique are major drawbacks. It is mainly due to weak bonds between particles leading to relatively poor strength of the parts. In addition, large sizes of powder particles cause rough surface finishes of objects. Similar to the SLS process, the removal of trapped powder particles inside small cavities can be difficult and these residues may be harmful to cells and tissues. Finally, there is still the issue of the shrinkage and distortion that can occur during printing and sintering steps (Roseti *et al.*, 2017; Thavornyutikarn *et al.*, 2014).

Bioprinting

Bioprinting is one of the latest developed additive manufacturing processes and can overcome some of the challenges met with conventional scaffolds manufacturing processes. Typically, conventional methods do not allow controlling cell distribution with accuracy and then cannot produce homogeneous scaffolds. In bioprinting, small units of cells and biomaterials are dispensed together with micrometer precision to build complex structures like tissues or organs (Fig. 4(a)). To date, bioprinting has been mostly used to process hydrogels and different types of cells. The current main technologies used for bioprinting are inkjet, microextrusion and laser-assisted printing. Inkjet printing delivers controlled volumes of a liquid ink to predefined locations onto a substrate in order to build the final construct. In this technique, thermal or acoustic forces are used to eject drops of liquid. The main limitation of inkjet bioprinting is that the biological material has to be in a liquid form to enable droplet formation and the liquid must form a solid 3D structure after deposition. Microextrusion works in a similar way than extrusion processes mentioned above with a robotically controlled extrusion of a material, which is deposited onto a substrate by a microextrusion head. Contrary to inkjet printing, microextrusion usually leads to beads or cords rather than liquid droplets. The major benefits of this technique are its ability to deposit high cell densities and the wide range of available materials. Many researches are now focused on increasing print resolution and speed which are the main limitations of microextrusion. In laser-assisted bioprinting, laser pulses are focused on a "ribbon" made of a laser-energy-absorbing layer and a layer of biological material. The laser generates a high-pressure bubble that propels cell-containing materials toward the collector substrate. Despite interesting advantages like the absence of nozzle avoiding clogging and its compatibility with a wide range of cells, rapid gelation kinetics are required to achieve high resolution and high shape fidelity. In all these three bioprinting processes, the most important factors are surface resolution, cell viability and the biological materials used for printing. Bioprinting is considered as promising approach in the field of

regenerative medicine to address the need for tissues and organs suitable for transplantation (Roseti *et al.*, 2017; Pina *et al.*, 2017; Murphy and Atala, 2014).

To conclude with scaffolds manufacturing techniques, Additive Manufacturing processes like SLA, FDM, SLS/SLM, 3DP and Bioprinting offer some benefits over conventional fabrication techniques. Indeed, they allow high flexibility in shape and size, precise control over spatial distribution and porosities, high reproducibility and customized design for specific medical applications. Moreover, a broad variety of biomaterials can be shaped with Additive Manufacturing. For the time being, SLA and FDM are widely studied to produce and optimize the manufacturing of scaffold architectures for bone tissue engineering applications. In fact, these two processes currently present the best characteristics for scaffolds fabrication. SLA has the best accuracy and surface quality while FDM allows versatile fabrication in lay-down pattern and good structural integrity. The proper fusion bonding between individual materials layers involved in these techniques is the reason why they can produce 3D structures with good mechanical integrity throughout the entire scaffold compared to powder-based systems.

Additive Manufacturing processes are probably going to replace conventional fabrication techniques for biomaterials scaffolds fabrication due to the poor control of the internal and external architecture, pore morphology, pore size, pore interconnectivity and overall porosity involved in these classic processes (Thavornyutikarn *et al.*, 2014; Roseti *et al.*, 2017).

Materials Functionalization and Drug Delivery Systems

As mentioned above, most of synthetic bone graft substitutes do not possess osteoinductive properties as natural-derived materials like demineralized bone matrix. This can be problematic in situations where the ideal graft environment is disturbed with an absence of bone growth factors secretion. Therefore, providing osteoinductive properties to graft substitutes is one of the major challenges of the recent and futures researches besides implant composition, structure and bioresorbability. The final objective is to design and develop temporary bone scaffolds able to deliver bioactive molecules and drugs or cells to the injury site and

Fig. 6 Techniques to load biomimetic ceramics with therapeutic agents/drugs.

promote the healing and tissue regeneration while concomitantly preventing pathology. For this purpose, the capacity for a scaffold to direct cell behavior can be improved through the controlled delivery of bioactive molecules like growth factors, stem cells, drugs and proteins. Indeed, these molecules can positively influence the bone mass by stopping the action of inhibitors and thereby have a positive effect on bone mass (Wang and Yeung, 2017b; Lin *et al.*, 2019; Alaribe *et al.*, 2016; Haugen *et al.*, 2020; Bongio *et al.*, 2010; Giannoudis *et al.*, 2007).

Different strategies are considered to boost bone repair like the application of biologically active molecules and the seeding of scaffolds with stem cells to create bone tissue engineered structures. The administration of such biomolecules has showed promising results in some preclinical and clinical models for the promotion of bone formation and repair. Moreover, the use of biodegradable scaffolds is preferred due to their contribution to the release of loaded bioactive molecules. According to the wide literature on the topic, combining resorbable scaffolds for tissue regeneration with drugs is a suitable strategy to improve tissue regeneration. In fact, such association combines different advantages. The first one is a local drug delivery with improved bioavailability allowing to reduce adverse effects with respect to systemic drug administration. Secondly, this allows a continuing drug release without interruption. Finally, there is the possibility to associate two or more drugs/bioactive molecules in a single scaffold in order to extend the current clinical utilities (Campana *et al.*, 2014; Wang and Yeung, 2017b; Alaribe *et al.*, 2016; Haugen *et al.*, 2020; Ho-shui-ling *et al.*, 2019).

Two important requirements for drug-releasing scaffolds are the appropriate dose providing over the suitable therapeutic time and the controlled biodegradability rate of the scaffold material. The first requirement needs to be tuned to dynamically match the physiological needs of the tissue regeneration. Similarly, scaffold degradation rate is crucial to control the drug release and should be synchronized with the rate of tissue growth (Giannoudis *et al.*, 2007; Kwong and Harris, 2008; Ho-shui-ling *et al.*, 2019; Alaribe *et al.*, 2016; Haugen *et al.*, 2020; de Grado *et al.*, 2018; Turnbull *et al.*, 2018; Diaz-Rodriguez *et al.*, 2018).

According to the as-cited requirements, polymers, ceramics and their composites are suitable materials for making drug-releasing scaffolds due to their properties. On one side, polymers possess a tunable biodegradation rate due to hydrolytically unstable linkages in their backbone in addition to being mostly biocompatible. Both natural and synthetic polymers can be associated with bioactive molecules which can be covalently bound to polymers or physically entrapped inside a polymer matrix. In both cases, the polymer degrades releasing bioactive molecules in the physiological environment. There are different forms of polymeric scaffolds for drug delivery from 3D porous matrices to electrospun nanofibrous matrices, nanoparticles, porous microspheres and thermosensitive hydrogels. The load of drugs in polymer scaffolds can be achieved by different techniques and the most common one is the blend loading which involves a previous blend of the polymer and the drug (Fig. 5(d)). Usually, the blending is made by mixing solutions of the polymer and the previously prepared drug in a common solvent. This strategy allows for the drug to be incorporated during the formation of the scaffold. The other well-known drug loading processes are soak loading (Fig. 5(a)), site-specific binding of the drug to the polymer (Fig. 5(e)), pre-loading in nano/micro-particles (Fig. 5(c)), and drug polymer conjugation (Fig. 5(b)). In the soak loading process, drugs are embedded in a pre-fabricated drug-free scaffold by submerging the scaffold in a solution of the drug until its loading. For the site-specific binding, polymers which present functional groups with affinity to drugs can build strong drug-polymer interactions for the loading. The pre-loading in nano/microparticles method consists of loading the drug in small polymer particles, and then confining it within the scaffold polymer networks during pre- or post- fabrication. Finally, the drug-polymer conjugation allows to bind the drug and the polymer in a covalent manner for a precise control of the quantity of the incorporated drug. Several parameters like the polymer-drug compatibility, the preparation method of the scaffold, drug stability, the final application, and the desired drug release rate are involved in the choice of the process. The drug release can then be controlled by various processes as a function of loading approach. These processes imply diffusion, polymer erosion or degradation, and swelling of polymer followed by diffusion. They can all take place simultaneously or not (Calori *et al.*, 2020; Kwong and Harris, 2008; Ho-shui-ling *et al.*, 2019; Alaribe *et al.*, 2016; Sabir *et al.*, 2009; Dorati *et al.*, 2017).

On the other hand, ceramic materials have also the ability to biodegrade (*e.g.*, CaP, bioglasses and calcium sulfate) and release bioactive molecules at a controlled rate. Actually, the incorporation of therapeutic molecules to bioceramics could enhance their

performance by ensuring tissue repair, treatment, and/or preventing post implantation pathologies or diseases by the controlled local delivery of loaded therapeutic agents. Multidimensional and hierarchical ceramics structures allow increasing the surface area of drug-releasing scaffolds and promoting proteins adsorption. Moreover, the incorporation of therapeutic molecules within the structure of bioceramics enables the administration of poorly water-soluble drugs without the need of any kind of additives. This combination can lead to a local and long-term effective drug release with ceramic resorption at the target site. In order to do so, different techniques are available to load biomimetic ceramics with therapeutic molecules: adsorption, physical entrapment, and covalent bonding (Fig. 6). Physical adsorption, which is a superficial phenomenon, is one of the most commonly used mechanisms to dope biomimetic ceramics with therapeutic molecules. This approach is clearly influenced by surface characteristics of the biomaterials as well as the drug loading capacity and release. High scaffold-specific surface areas allow the loading biomolecules without the use of aggressive treatments. However, surface adsorption doesn't usually achieve a long-term retention of drugs due to the weak interactions between biomaterials and therapeutic molecules. The second technique consists in trapping therapeutic molecules into the structure of the material during their manufacturing. The key of this process is an optimal homogenization of the drug inside the scaffold matrix to avoid the burst release. This category of loading processes requires a multistep approach that complicates the synthesis of the scaffold. The last approach to produce drug-loaded ceramics scaffolds is the covalent bonding of therapeutic molecules. It can achieve stable and durable incorporation for up to several months and avoid the burst release (Dorati *et al.*, 2017; Chindamo *et al.*, 2020; Lin *et al.*, 2019; Ho-shui-ling *et al.*, 2019; Alaribe *et al.*, 2016; Diaz-Rodriguez *et al.*, 2018).

The study of drug-releasing scaffolds is a promising area for both polymers and ceramics. Indeed, the incorporation of therapeutic molecules or cell attachment to these systems can allow to increase the performance and so the potential applicability of the scaffolds. Researches are focused on the finding of the biomaterial or a combination of biomaterials with optimum properties to support tissue regeneration, and to obtain drug delivery systems able to modulate drug release. For that, the dreamed drug-loaded scaffolds must meet the following conditions: a local drug delivery with improved bioavailability and reduced adverse effects with respect to systemic drug administration, a sustained drug release and the ability of combining two or more drugs in a single scaffold. There have been continued advances towards the further development of the field where new materials and combinations of materials, as well as improved scaffold designs and novel processing techniques have been investigated for drug-delivery.

Still, there is a lack of a large amount of biological information to fully understand the *in vitro* and *in vivo* performance of such scaffolds in specific applications. Finally, too few clinical trials are made on these studied systems due to strict regulations. In order to limit the gap between academic research and commercial reality more efforts must be made to achieve an application and clinical use (Bohner, 2014; Mourin and Boccaccini, 2010; Bagherifard, 2017; Alaribe *et al.*, 2016; Diaz-Rodriguez *et al.*, 2018).

Conclusion

The twentieth and beginning of twenty-first century brought considerable advances in the field of bone tissue engineering. The growing and never-ending needs coupled with the motivation of the researchers for innovation, have contributed intensively to develop more and more smart strategies for bone substitution. Future research should be based on interdisciplinary and convergence of several sciences and technologies, for simultaneous optimization of chemical composition control, shaping methods and functionalization routes.

New Trends in Ceramics for Orthopedics

State of the Art

Ceramics were successfully introduced in orthopedics at the end of the 1960s. Ceramics, in contrast to metals or polymers do not suffer corrosion or hydrolysis. Moreover, their resistance to wear makes them ideal for bearing devices. So far, the major industrial applications of bio-ceramics have been femoral heads and cups, hydroxyapatite coatings in total hip arthroplasty, and bioactive ceramics as bone fillers. Ceramics can be chosen either for their inertia and wear properties (for joint prostheses), or for their affinity with bone tissues, which favors bone adhesion and bone in-growth. They are therefore separated in two groups: 'bio-inert' and 'bio-active' ceramics.

Currently used bio-inert ceramics, i.e., micro-structured alumina, yttria stabilized zirconia, and mostly now zirconia-toughened alumina composites give satisfactory results. Their major biomedical application concerns Total Hip Replacement (THR), especially for the femoral head and acetabular cup components. Nowadays, the main issue for THR is the generation of wear debris, produced mainly by the acetabular component ([Campbell et al., 2004](#)). The standard artificial joints consist of a polymer cup made of ultrahigh molecular weight polyethylene (UHMWPE), placed in the acetabulum via a metal-back component, and a metal (stainless steel or cobalt chromium alloy) ball affixed to a metal stem introduced in the femur. Any use of the joint, such as walking, results in cyclic articulation of the polymer cup against the metal ball. During the reciprocating motion of normal joint use, UHMWPE fibrils are then released, mostly by adhesive wear, to form submicrometer-sized wear debris. This results in billions of tiny polymer particles being shed into the surrounding synovial fluid and tissues. The biological interaction with small particles in the body then becomes critical. It is currently believed that the UHMWPE particles generated at the contact surfaces enter the periprosthetic tissues where they trigger macrophages reaction. Then macrophages release pro-inflammatory cytokines that stimulate osteoclastic bone resorption, leading to osteolysis and eventual loosening of the prosthesis and a need for revision. This has led to the development and use of alternative surfaces for hip articulation such as ceramic-UHMWPE, metal-metal and ceramic-on-ceramic couplings. In the case of metal-metal coupling the amount of ion release can be very detrimental for the surrounding tissues. The use of bio-ceramic materials, in comparison to metal alloy structural implants, reduces wear rate of the polyethylene components and produces negligible amounts of metal ion release. Due to the low roughness exhibited by ceramic heads (typically lower than few nanometers) and their good wettability, abrasion is reduced significantly if ceramic femoral heads are used with acetabular cups made of polyethylene and almost completely avoided when using ceramic femoral heads together with ceramic cup inserts.

The clinical success associated to the use of ceramic led to the implantation of more than 3.5 million alumina components, more than 600,000 zirconia femoral heads worldwide since 1990, and more than 8 million zirconia toughened alumina components, with a strongly growing market (i.e., more than 25% growth for the alumina-alumina coupling between 2002 and 2004). There are many reports on fracture rates associated with ceramics. Important references have been compiled elsewhere ([Campbell et al., 2004](#)). If, in the pioneering days, the fracture rate was quite high (up to 13% for some series), the in vivo failure rate reported by the producer of BioloX® alumina is today below 0.01% ([Willmann, 2000](#)). A comparable failure rate was claimed by the producer of Prozyr® zirconia heads ([Cales, 2000](#)) before the critical event of 2001, discussed below. For more current ZTA ceramics, such as BioloX® Delta the failure rate is even lower, below 1 in 100,000 ([Ruys, 2019](#)).

Even though the clinical follow up with current alumina ceramics is very good, it must be kept in mind that their use has been restricted so far to a limited number of designs of hip components, for which the mechanical loading is less demanding. As an example, 22 mm heads are not currently manufactured using alumina ceramics, for reliability reasons. Alumina is not used for Total Knee Replacement (TKR), where ceramics could also improve the wear properties. Alumina-alumina coupling also exhibits a significant increase of failure ratios. This is again related to its modest mechanical properties. In the 90's, Yttria-Stabilized Zirconia became a popular alternative to alumina as structural ceramic because of substantially higher fracture toughness and strength. The use of zirconia has opened the way towards new implant designs that were not possible with alumina, more brittle. An example is the use of zirconia for 22 mm heads, and the development of zirconia knees by some companies. Biomedical grade zirconia exhibits the best mechanical properties of single phase oxide ceramics: this is the consequence of phase transformation toughening, which increases its crack propagation resistance. The stress – induced phase transformation involves the transformation of metastable tetragonal grains to the monoclinic phase at the crack tip. It is accompanied by volume expansion and induces compressive stresses which hinder crack propagation. On the other hand, due to this meta – stability, zirconia is prone to aging in the presence of water ([Chevalier, 2006](#)). Zirconia manufacturers considered this problem as a minor issue until 2001, when roughly 400 failures of zirconia heads were reported within a very short period (See Relevant Websites section). The failure origin is now associated to an accelerated aging in two particular batches. Even if limited in time and number, and clearly identified to be process controlled, these events have had a catastrophic impact for the use of zirconia, some surgeons returning to other solutions. More important, some clinical reports show that zirconia can exhibit a progressive ageing degradation even under 'normal' situation, which limits the long-term stability of zirconia.

For these different reasons, there is a trend to develop stronger and more reliable ceramics that should expand the field of application of bio-inert ceramics in orthopedics.

Unlike bio-inert ceramics, the requirements for bio-active ceramics are to provide favorable surfaces for bone adhesion and bone in-growth (Hench, 1998). On the other hand, the specifications in terms of load-bearing capability are less demanding. The bio-active ceramics are thus based on calcium phosphate materials (mainly hydroxyapatite, HAP, and tri-calcium phosphate, TCP), because their composition is close to the mineral part of bone.

Since the early 1980s, the most important application of bio-active ceramics has been the coating of orthopedic metal implants, at locations where a strong interface with bone is required. This is the case of some parts of the femoral stems and acetabular metal-backs for the hip joints and tibial and femoral components for the knee joints. These systems represent successful alternatives to cemented prostheses, especially for young and active people, and are therefore generally associated to ceramic-ceramic couplings. If clinical studies show a benefit concerning the early fixation of un-cemented implants compared to cemented artificial joints, no influence on implant lifetime has been measured so far (See Relevant Websites section). If most of current bio-active coatings are made of plasma-sprayed hydroxyapatite, new developments include new materials and/or new processes (Campbell, 2003). Newest approaches (i.e., biomimetic coatings) open the way to incorporate biologically active agents.

In the mid 1980s, the osteo-conductive properties of calcium phosphate led to their use as synthetic bone grafts, as an alternative to auto-grafts and xeno-grafts (Hench, 1998). Indeed, as compared to auto-grafts, synthetic bone substitute involve less invasive surgery (a two step operation is necessary for the former) and are available in large quantities. As compared to xeno-grafts, the risk of rejection is much less important, and the transmission of diseases is avoided. Most of current bone substitutes are porous pieces of biphasic calcium phosphates, i.e., HAP-TCP composites (Daculsi *et al.*, 2003). A careful control of the architecture (volume and morphology of the macro and micro-porosities) is a key issue for a successful implant, as the macroporosity controls the access of the tissues and biological fluids to the volume of the substitute, and the microporosity the adhesion of the cells and the resorption rate of the calcium phosphate (thus the availability of Ca and P ions for bone reconstruction). The fast *in-vivo* resorption rate of TCP, as compared to HAP, allows controlling the overall degradation rate of the HAP-TCP composite, and thus adapting the material to the patient (faster resorption for patients with faster bone reconstruction). The synthetic bone substitutes US market was about 280 million USD in 2015, with an expected 20% yearly increase (Bone Graft Substitutes Market).

Although they offer very good clinical results, some limitations still exist. The optimization of the micro- and macro- porosities and their effect on biological properties are not always taken into account, which results in a large variability of physico-chemical properties among current commercial substitutes. Another strong limitation is their brittleness associated to low toughness and slow crack growth sensitivity (Benaqqa *et al.*, 2005), which restricts their use to non-load bearing applications, and makes them difficult to handle during surgery. Last but not least, their bioactivity should be increased in order to promote a faster and better bone reconstruction. We should keep in mind that the nanostructure of natural HAP crystals leads to a specific area of bone around 50–100 m²/g, to compare with 1 m²/g for most synthetic bone substitutes (grain size being generally higher than 1 µm).

New Progresses on Bio-Inert Ceramics

From Alumina to Plastic Alumina-Zirconia Composites

The first used bio-inert ceramics, i.e., alumina and zirconia, give good clinical results, especially compared to metals and polymers. New generations of ceramics for orthopedics should meet the need for a larger range of devices and a better reliability. The state of the art, described above has shown the limit of alumina in terms of mechanical performance and of zirconia in terms of long-term stability. Zirconia-Toughened alumina (ZTA) usually performs better than alumina in terms of mechanical strength, at least equaling the strength of zirconia while presenting a much better physico-chemical stability under *in vivo* conditions. As a result, ZTA is now the reference ceramic materials for the fabrication of hip replacement balls and cups. Major ceramic companies are developing such materials, of which a comprehensive state of the art is presented by Piconi (2017). Among them, the Biolox® Delta material developed by Ceramtec AG (Plochingen, Germany) has become the most implanted ceramic material in orthopedics (with more than 8 million components). It consists of approximately 75% aluminum oxide, the basis for hardness and wear resistance, and approximately 25% zirconium oxide, for improved mechanical properties (See Relevant Websites section). A strength value higher than 1150 MPa is reported associated with a toughness value of 8.5 MPa√m. Other zirconia-alumina composites are already commercialized but did not reach comparable market penetration. For example, the alumina-toughened zirconia (ATZ, 80% tetragonal zirconia polycrystals and 20% alumina) Bio-Hip®, developed by Metoxit AG (Thayngen, Switzerland), has a bending strength of up to 2000 MPa, and a toughness of 8 MPa√m. Two materials commercialized by Mathys Orthopädie GmbH are also worth mentioning: a ZTA (Symarec) and an ATZ (Ceramys), both with interesting balance between strength and hardness. Table 1 summarizes some typical mechanical properties of current alumina-zirconia composites, compared to monoliths.

However, the major parameter controlling ceramics lifetime is their sensitivity to Slow Crack Growth (SCG) and delayed failure, which is not taken into account in the sole strength and toughness data. As a general trend, the susceptibility of ceramics to SCG is discussed on the basis of a V (crack velocity) versus K_I (stress intensity factor) diagram (K_I representing the stresses at the tip of a crack or any pre-existing defect such as a pore, a scratch, etc, in the ceramic). Recently, the presence of a threshold in the stress intensity factor, below which no crack propagation occurs, has been the subject of important research in the ceramic field. This

Table 1 Mechanical properties of current alumina-zirconia composites, compared to monoliths

Material	Alumina BioloX®	Zirconia Prozyr®	ZTA (BioloX delta®)	ATZ (Ziradent®)	Pseudo-plastic ceramic (Evocera®)
K_{IC} (MPa $\sqrt{m}$)	4	6	8.5	8	8–14
Flexural Strength (MPa)	800	2000	1384	> 1300	500–700
Yield strength (MPa)					400
Young modulus (GPa)	400	200	398	~ 220	
Hardness (Vickers)	1500	1200	1900	1400	

ZTA: zirconia-toughened alumina.

ATZ: alumina-toughened zirconia.

*All information and data correspond to the present state of our knowledge concerning the properties of the ceramics. They are given by the producers and may not be measured using comparable setups, therefore they are given only as orders of magnitudes.

Fig. 1 V- K_I curves of biomedical grade alumina and zirconia and of two generations of alumina – zirconia composites. The insert shows the microstructure of a novel composite with nanometric zirconia particles inside the alumina grains (nano-zirconia toughened alumina).

threshold corresponds to equilibrium with null crack velocity. For ceramic joint prostheses for example, this threshold, K_{I0} , determines a safety range of use. **Fig. 1** represents the overall V- K_I curves of biomedical grade alumina, zirconia and an alumina – 10 vol% zirconia composite obtained by a modified colloidal route (De Aza *et al.*, 2002). It shows the significant improvement brought by these composites on both K_{IC} and K_{I0} .

The addition of alumina to zirconia at least reduces drastically ageing kinetics. It is shown that strength of BioloX delta® for example does not decrease even when repeatedly steam sterilized. However, ‘no decrease in strength’ does not mean necessary ‘no ageing’, since other manifestations of ageing are grain pull out and roughening. Some studies have been devoted to ageing in alumina–zirconia systems, and they show that, even if limited and possibly reduced to zero, some degree of degradation can be observed, depending on microstructural features. However the consequences of ageing in alumina-zirconia composites seem less important than in zirconia monoliths. As an example, we showed in a previous work (Pecharroman *et al.*, 2003) that ageing could be significant in a 3Y-TZP–alumina composite above 16 vol% zirconia (see **Fig. 2**). This critical content was related to the percolation threshold above which a continuous path of zirconia grains allowed transformation to proceed. Any extrapolation to other laboratory scale or industrial composites could be hazardous, but it shows again how ageing must be checked carefully prior to clinical development of a given alumina–zirconia composite.

Towards Pseudo-Plastic Ceramics

The reinforcement in conventional alumina – zirconia composites is due to the zirconia phase transformation toughening mechanism. Other sources of reinforcements can be expected in nano-structured ceramics and composites, such as the development of a compressive residual stress field due to the homogeneous distribution of second phase nanoparticles in a matrix. This is the case of a composite, where zirconia nanoparticles are evenly distributed into a micron size alumina matrix (Chevalier *et al.*, 2005). Those zirconia particles are mainly (> 70%) intragranular, with almost perfect spherical shape (diameter ranging from 30 nm to 150 nm).

Fig. 2 Aging behavior of alumina – zirconia composites : zirconia monoclinic fraction observed after 40 h aging at 140°C versus zirconia content in the composite.

These particles are well below the critical size for phase transformation. This composite was developed in the framework of Bioker project (FP5 – Contract n° G5RD-CT-2001-00483). The V-K_i curve of this composite, containing only 1.6 vol% of zirconia nanoparticles, is compared to alumina and zirconia monoliths, and to the previous microstructured composite on Fig. 1. The nanostructured composite exhibits a peculiar behavior, i.e., its toughness is very high (50% higher than alumina, with the addition of only 1.6 vol% of zirconia!) and its sensitivity to Slow Crack Growth is much lower than for the other materials (ratio of threshold to toughness close to a covalent ceramic). This leads to a threshold value twice that of a standard biomedical grade alumina.

The literature is still sparse concerning mechanical properties of nanostructured ceramics and composites, especially in regards to orthopedic applications (in which field nanostructured ceramics are not yet on the market). However, some recent works (Lee *et al.*, 2003) show a significant improvement of both wear resistance and toughness associated to the use of dispersion of nanometer sized particles in a micrometer size matrix. This kind of materials is usually called ‘micro- nano’ composites, and can be processed via classical sintering methods. The process of ‘real’ nano- composites (both phases being less than 100 nm) is now possible via new sintering techniques such as Spark Plasma Sintering. However, their potential for orthopedic applications is still speculative.

One can also take advantage of Zirconia tetragonal-to-monoclinic phase transformation to fabricate pseudo-plastic ceramics (Chevalier *et al.*, 2020). This is one of the most interesting advances in the field these last years. This pseudo-plastic effect rises from the transformation-induced plasticity allowed by the t-m transformation, and was first observed in ceria-stabilized zirconia (Ce-TZP). Recently, an optimized material was proposed. It’s composed of 84 vol% ZrO₂ doped with 11 mol% of Ceria, 8 vol% Al₂O₃ and 8 vol% SrAl₁₂O₁₉ platelets. Together with an adequate sintering schedule (setup to offer a grain size and phase assemblage favoring the t-m transformation a little below room temperature (– 42°C)), this results in an excellent tolerance to flaw (as illustrated in Fig. 3 that shows almost no decrease of strength in the presence of defects as large as 150 µm) related to a plastic strain to failure of ~0.5%. However this is at the cost of a largely reduced strength (~400 MPa).

Although no applications of this material are on the market, it is available from the Doceram company under the tradename EvoCera® (EVOCERA), and is believed to be an excellent candidate for the fabrication of dental implants.

New Implant Designs

The benefit arising from alumina – zirconia composites and nano-structured materials permitted to develop new hip implant designs that are in the scope of orthopedic surgeons, to increase the quality of life of patients:

- Thinner acetabular cup wall for ceramic-ceramic making the procedure as conservative regarding bone removal as the current metal-metal solution. Ceramic/ceramic implants are currently much bulkier than the equivalent metal component.
- Small heads (22 mm, 28 mm) with longer neck length than currently available for surgeons.
- Hip resurfacing implants, making surgery much less invasive than today.

These last years, three concepts also emerged and are marketed:

- Femoral and tibial component of primary, total knee replacements (TKR).
- Anatomically-contoured heads for hip implants (tradename Biolox contoura® (Varadarajan *et al.*, 2013).

Fig. 3 Stress-strain curve of a pseudo-plastic ceramic with and without defect. From Chevalier, J., Liens, A., Reveron, H., *et al.*, 2020. Forty years after the promise of «ceramic steel?»: Zirconia-based composites with a metal-like mechanical behavior. *Journal of the American Ceramic Society* 103, 1482–1513.

- Systems for revision surgery (specifically ball head exchange), in which a titanium sleeve is used between the remaining stem and the new ceramic ball, to accommodate small geometric defects of the stem and avoid its replacement (*Biolog Option® System*).

Improved Testing Methods

As can be seen above, most biomedical ceramics are characterized by their strength, toughness, hardness, sometimes by their resistance to slow crack growth or hydrothermal ageing. Additionally, their resistance to friction and wear are fully characterized, using hip simulator that reproduces the gait movements, including now the shocks due to microseparation and relocation of the head in the insert in the case of hip prostheses components (Al-Hajjar *et al.*, 2013).

However, most testing procedures measure a given property individually: interactions between the different properties are seldom taken into account. A few studies start to consider the interactions between wear and hydrothermal ageing (Gremillard *et al.*, 2013; Perrichon *et al.*, 2017; Al-Hajjar *et al.*, 2019) and show the existence of an acceleration of ageing on the most loaded areas, as well as an acceleration of wear on the areas most degraded by ageing. These two degradation processes are thus symbiotic and should be studied as such.

Current Developments on Bio-Active Ceramics

Two physical properties of bio-active ceramics control their overall behavior, thus are key parameters for optimum biological performance. These are the interconnecting macro-porosity and an appropriate micro-porosity. The literature is still very sparse on these points, although their control is quite easy (Bignon *et al.*, 2003).

In the previous decade, macroporosity ($> 100 \mu\text{m}$) is generally obtained through the incorporation, in the green ceramic body, of a volatile phase (i.e., polymer), which is burnt during a thermal treatment at intermediate temperature. The amount and size of this porogen agent directly controls the size of the macro-pores, and more important their interconnections. The characterization of these interconnections can be obtained via mercury intrusion porosimetry measurements or image analysis (an example being images obtained with X-ray tomography).

Additive manufacturing techniques are now particularly useful to address both an optimization of the characteristics of the macroporosity (Charbonnier *et al.*, 2020; Magnaudeix *et al.*, 2016) and of the external shape of the scaffold, enabling the fabrication of personalized bone substitutes (Brie *et al.*, 2013), potentially leading to accelerated recovery and spectacular aesthetic results (Fig. 4).

Micro-porosity ($< 2 \mu\text{m}$) is controlled by the sintering procedure: higher temperatures and sintering times decrease the volume, and to lower extent the size of micro-porosity. The size of the micro-porosity is mainly related to the grain size of the ceramic powder prior sintering. Nanostructured ceramic powders could open the possibility to obtain pores with a sub-micrometer size and to increase specific surface.

Although the effect of interconnections between macro-pores is clearly established (i.e., faster proliferation of cells and subsequent bone in-growth), the role of micro-porosity is not yet completely established. Some results show that the micro-porosity is beneficial for cell adhesion and even invasion (Bohner *et al.*, 2017) and to some extent to osteo-induction (Habibovic *et al.*, 2005). This should still be an important field of research.

Fig. 4 Fabrication steps of patient-specific implants. From Brie, J., Chartier, T., Chaput, C., *et al.*, 2013. A new custom made bioceramic implant for the repair of large and complex craniofacial bone defects. *Journal of Cranio-Maxillo-Facial Surgery* 41, 403–407. doi:10.1016/j.jcms.2012.11.005.

As an alternative to biphasic calcium phosphates, there is a renewed interest on the use of bioactive glasses, in the form of porous architectures for bone substitution applications (Chen *et al.*, 2006). Bioactive glasses, such as 45S5 Bioglass®, which was developed more than 20 years ago, meet the criteria to be used as bone substitutes: they are osteo-conductive, bioactive, and at least partially resorbable. The major advantage of bio-active glasses is the formation, in contact with body fluids, of a carbonated apatite layer, with physico-chemical features close to natural bone hydroxyapatite (Hench, 1998). This apatite is characterized by nanometer size, non-stoichiometric and partially amorphous grains. In addition to the possible modification of micro-porosity via sintering temperatures and macro-porosity via porogen addition, bio-active glasses offer the opportunity to tailor their bio-activity and mechanical properties via crystallization process. Indeed, at intermediate temperature, i.e., between glass transition and melting temperatures (around 550°C and 1000°C for Bioglass®) the crystallinity ratio can be varied from 0 to almost 100% and the size of the crystals from nanometric to micrometric values. Therefore, ‘ideal’ resorbable scaffolds offering a range of porosity between nanometers and hundreds of micrometers, with large specific surface, can be obtained with bioactive glasses. There is still very few clinical uses of porous bioactive glasses as monolithic materials in orthopedics. However, they are available as granules or putty (for ex. Glassbone® Putty). They are also used as bioactive loads in PLA-bioactive glasses composites: some orthopedic fixation devices take advantage of the good mechanical properties and of the resorbability of the composite (for ex: LockActiv® interference screws).

In addition to be a “physical” substrate for bone formation, porous ceramic bone substitutes can sustain other functionalities. Mainly, they can locally release biologically active substances with controlled kinetics. Research is conducted mainly on two kinds of substances: antibiotics to avoid inflammation around the implant (Hasegawa *et al.*, 2004), and growth factors (Williams, 2006) such as Bone Morphogenetic Protein to enable a faster growth of bone. The key factor controlling the drug release is the way the drug is held in the implant. Much work is dedicated to include drugs in resorbable polymers. The release rate is then controlled by either the resorption rate of the polymer or the diffusion of the drug through the polymer. The polymer can then be added to a ceramic matrix, or mixed with calcium phosphate or bioactive glass powder to produce a polymer matrix composite (Tampieri *et al.*, 2003). Another possibility is to include directly the drug in the pores of the porous ceramic implant. Such systems allow tunable release rate for periods arranging from hours (Polak *et al.*, 2017) to several weeks (Dash and Cudworth, 1998), the release rate depending on the structure of the porosity (size and connectivity of the micropores) and on the drug physical properties (mainly diffusion coefficient and adhesion energy with the bone substitute).

Due to the continuous release and precise location, the efficiency of the antibiotics is optimum with very small doses (but locally almost constant and higher than the Minimum Inhibitory Concentration for the most common pathogenic agents). It has been shown also that bone substitutes loaded with growth factors present a bone growth rate that can be fourfold this of non-loaded substitutes. The addition of a drug-delivery functionality to bone substitutes can be considered as very promising for faster healing. However, the higher cost of such Drug Delivery Implants still impedes their clinical use.

One can go a step further into complexity, by synthesizing implantable materials that are partly living tissues. After Williams (2006), “tissue engineering is the creation of new tissue for the therapeutic reconstruction of the human body, by the deliberate and controlled stimulation of selected target cells, through a systematic combination of molecular and mechanical signals”. In other words, artificially building new tissues requires a delicate combination of starting material (cells) and interactions with the biological reactor. The presence of a scaffold mimicking the Extra Cellular Matrix can be considered as an essential factor, from both mechanical and molecular points of view. Indeed, the scaffold should not only provide the place for the cells to live, but also favors the different cellular process that have to take place (differentiation, proliferation, building of new ECM...). To our knowledge, such scaffolds do not yet exist.

Calcium phosphate ceramics are candidates for such applications, because of their ability, when combined with molecules such as Recombinant Human Bone Morphogenetic Proteins (rhBMP2), to induce bone formation even in ectopic sites (Kroese-Deutmann *et al.*, 2005). Much research is also devoted to polymer matrix composites (loaded with calcium phosphate particles, BMPs and possibly cells), an interesting way to produce the scaffold being to use 3D printing, rapid prototyping or similar techniques to control exactly its morphology and the distribution of the different components.

Conclusion

The aim of this paper was to review current research and development on ceramics for orthopedics. Alumina-zirconia composites are brought to the market as an answer to alumina brittleness and zirconia aging. Furthermore, new processing technologies open the way towards nanostructured ceramics and composites that are expected to exhibit improved mechanical performances.

Concurrently, bio-active ceramics bone substitutes are increasingly associated to organic materials and biological agents, to improve bone in-growth. Bone tissue engineering is still far from daily use, but concrete trends can be distinguished.

New Trends in Ceramics for Dentistry

Paola Palmero, Department of Applied Science and Technology, Politecnico di Torino, Italy and The Polytechnic University of Turin, Torino, Italy

© 2021 Elsevier Inc. All rights reserved.

Introduction

The human tooth is essentially an inorganic/organic composite material, characterized by a complex hierarchical structure, which is responsible of its unique physical, mechanical and optical properties. A deep understanding of the relationship between the composition, the structure and the properties of human teeth is necessary for correctly designing restorative dental materials and products.

Basically, the bulk of the dental tissue is composed by thick, mineralized dentin, covered by a protective layer, the highly mineralized enamel. These two layers are joined by the so-called dentin-enamel junction (DEJ) (McKittrick *et al.*, 2010). The root, mainly composed by dentin, is attached to the bony socket through a cementum. The inner part of teeth is composed by a non-mineralized soft tissue, the dental pulp that also contains nerves and the vascular system to provide connection with the surrounding tissues (Goldberg *et al.*, 2012; McKittrick *et al.*, 2010).

Dentin and enamel differ on their chemical composition and micro/macro-structure.

Dentin contains 40–45 vol% mineral phase (apatite crystals), 30 vol% organic matter (collagen and other proteins) and 20–25 vol% water. Enamel is richer in mineral phase (~ 92 vol%), with a smaller fraction of organic material (2 vol%) and water (6 vol%) (Goldberg *et al.*, 2012; McKittrick *et al.*, 2010).

Dentin's architecture is mainly formed by tubules (~ 1.5 μm in diameter), surrounded by highly mineralized apatite (0.5–1 μm in thickness) rods, which extend from the DEJ to the pulp (Halgas *et al.*, 2013; Cuy *et al.*, 2002). Enamel is mainly composed ~ 5 μm keyhole-shaped structures known as prisms (Lu *et al.*, 2012), which extend from the DEJ to the tooth surface. Fig. 1 depicts the characteristic microstructures of both dentin and enamel tissues of human tooth (Chan *et al.*, 2011).

Due to different compositions and structures, dentin and enamel are characterized by different mechanical properties and therefore show different roles during the mastication process. Dentin, located between the crown and the root, has the role of distributing the load across the teeth; enamel, the hardest tissue in human's body, protects the dentine from fracture and wear damage during load-bearing function, and acts as the cutting and grinding surface during mastication. For this reason, teeth are required to have high hardness and stiffness to support the mastication load, while a certain fracture toughness is required as well, to limit cracks and brittle fracture.

Mechanical properties of dental and enamel structures are frequently determined by nanoindentation tests, able to provide hardness and stiffness data. Halgas *et al.* (2013) performed a systematic investigation of dental mechanical properties by moving from the enamel occlusal surface to dentin tissue, passing through the DEJ. Nanoindentation tests proved that tooth is characterized by the highest hardness and indentation modulus in the enamel layer, and specifically in correspondence to the occlusal surface. Here, in fact, the hardness and modulus were about 6.5 GPa and 90 GPa, respectively. These values decreased to about 3.5 GPa and 75 GPa, respectively, in the areas closed to DEJ. Crossing the DEJ, a further sharp reduction was observed, since hardness and indentation modulus were about 1 GPa and 20 GPa, respectively, in the dentin region. Here, such values were almost constant and independent from the indentation area. Cuy *et al.* (2002) performed a deeper investigation of the enamel mechanical properties, and confirmed that the hardness and the elastic modulus were higher at the enamel surface and decreased significantly in correspondence of the DEJ. These authors correlated the variations in mechanical properties to changes in enamel chemical composition and microstructure (enamel prisms orientation). In particular way the chemical composition played the major role, since it was found a Ca and P enrichment at the enamel surface, suggesting a higher degree of mineralization in this area. In spite the sharp variation of mechanical properties in correspondence of the DEJ, this interface has a key role on the overall performance: it is very durable, and able to inhibit the propagation of cracks from the enamel to the dentin as well as to keep the tooth integrity during masticatory actions (Imbeni *et al.*, 2005).

Ceramics should satisfy some requirements to be clinically approved as dental materials, which include mechanical properties, biocompatibility and aesthetical properties. Some of these requirements, such as those related to mechanical performance and biocompatibility, have been addressed by specific standards. In particular way, the standard ISO 6872–2015 can be considered a reference for some physical and mechanical properties. Here, besides specific definitions of dental ceramic products, ceramics are classified into Type I, which includes ceramic products in the form of powders, pastes, or aerosols, and Type II, which are all other forms of ceramic products. In addition, the required minimal mechanical (flexural strength and fracture toughness) and chemical (solubility) properties for the different ceramic products are given, in agreement with their intended chemical use. To make an example, the recommended minimum flexural strength and fracture toughness of a monolithic ceramic for single-unit anterior prostheses, veneers, inlays, or onlays adhesively cemented are 50 MPa and 0.7 MPa $\sqrt{\text{m}}$, respectively, whereas the solubility should be < 100 $\mu\text{g}/\text{cm}^2$. For the determination of the flexural strength, three testing methods are recommended by this standard: three- and four-point bending and biaxial flexure (piston-on-three-ball); the recommended fracture toughness method is the Single-edge V-Notch Beam (SEVNB) test.

The evaluation of biocompatibility of the dental medical devices is described in the standard ISO 7405–2018, even if it is not specific for ceramic materials and products. This standard provides a clear guide to select the most proper testing method - both *in-vitro* (cytotoxicity) and *in-vivo* (animal) tests - according to the contact nature and duration as well as to the dental device type. When possible, for ethical issues, *in-vitro* testing should be preferred to *in-vivo* ones, and for this reason the optimization of laboratory protocols aimed to mimic as much as possible the clinical practice is currently in course. *In-vitro* tests offer several advantages as compared to *in-vivo* ones: lower cost, higher reproducibility, no legal and ethical issues. By exposing the synthetic dental materials to different physiological fluids and/or cell cultures, it is possible to gain information about cytotoxicity, inflammatory responses, anti-bacterial properties or cell differentiation capability of the dental material itself (De Souza Costa *et al.*, 2014). A recent approach deals with the use of an artificial pulp chamber, allowing the contact of the pulpal surface of the prosthetic material with the culture media. In these tests, it is also very important to properly select the cell lineages, to possibly apply 3D culture models and properly select volumes and concentrations of cell cultures to approach as much as possible the clinical conditions (De Souza Costa *et al.*, 2014). *In-vivo* tests – performed to observe the response of the synthetic material to living tissues – involve the use of animals, thus involving ethical and legal controversies. Moreover, the information obtained by these tests can be affected by the species, age and gender of the animal used, the results could be difficult to interpret and not easily transferred to human beings.

A further important requirement for dental ceramics is the esthetics, meaning the color and the optical property of the material, trying to match as much as possible the natural dental issue. Since there is no standard defining the color, proper measuring systems are normally used. One of them, named CIE $L^*a^*b^*$ seems proper to characterize non-self-luminous objects. In this system, the color is given by three coordinates, where L^* gives the degree of brightness, a^* the redness/greenness and b^* the yellowness/blueness. These parameters can be evaluated by a spectrophotometer, allowing to quantify which is the mean color difference between two materials (*i.e.*, natural and synthetic tooth). The standard of clinically acceptable ΔE^* was determined as 3.7 (Kim *et al.*, 2014).

The physical, mechanical and esthetic requirements of all-ceramic dental materials restrict the choice to few compositions. In the following paragraphs, the current and mainly used materials for all-ceramic restorations are discussed, by summarizing their main characteristics, advantages over other solutions, current issues. Is to overcome such issues that new solutions – in terms of both materials and technologies, are nowadays under development, and they will be here discussed as well. Therefore, this contribution aims at providing some guidelines for the design and development of innovative all-ceramic products and at indicating the new directions that the research in the field of all-ceramics restorative materials is moving in.

Fig. 2 Classification of all-ceramic materials for dental restoration. Adapted from Ho, G.W., Matinlinna, J.P., 2011. Insights on ceramics as dental materials. Part I: Ceramic material types in dentistry. *Silicon* 3, 109–115.

All-Ceramic Dental Materials: State of the Art

According to the classification proposed in [Fig. 2](#), all-ceramic restorations can be distinguished into glass-matrix, glass-ceramics and polycrystalline ceramics, where not only the chemical composition but also the degree of crystallinity and the particle size can affect both the biomechanical properties and esthetics. In fact, highly esthetic ceramics contain a significant amount of glassy phase, but their strength is much lower than polycrystalline materials ([Kelly and Denry, 2008](#)).

The most traditional all-ceramic restorative material is the feldspathic one, which basically contain silica glassy phase (silica or silicate ≥ 15 wt%) ([Ho and Matinlinna, 2011](#)) and is commonly known as “porcelain”, which is referred to a mixture of quartz, kaolin and feldspar in a specific compositional range ([Babu et al., 2015](#)). All three components play specific roles: kaolin acts as a binder between the ceramics particles, but – due to its opaque appearance, its content in the mixture should be limited ($< 4\%$) ([Ho and Matinlinna, 2011](#)). Feldspar provides most of the glassy phase, while quartz acts as a reinforcement, since its structure does not change during the sintering process. Besides high chemical resistance and biocompatibility, the major advantage of this type of material is the very pleasing esthetics, since color and shade match those of natural dental tissue, and make it fine for veneers and inlays/onlays ([Ho and Matinlinna, 2011](#)).

Glass-ceramics or particle-filled glasses differ from traditional feldspathic materials due to higher degree of crystallinity, which improve their mechanical properties. During firing, a progressive crystallization occurs, thus leading to a material with 50 up to near 100% crystalline phase, with the remaining amorphous phase filling the porosity, and contributing to increase the density. Current glass-ceramic dental materials include three main compositions: leucite-reinforced glass-ceramics, lithium disilicates and fluorapatite-based ceramics ([Gracis et al., 2015](#)). The main advantages of the first two compositions rely on the higher mechanical properties as compared to porcelain, which widen their application to anterior/posterior teeth, crowns, all-ceramic bridges ([Ho and Matinlinna, 2011](#)). In particular way, leucite-based ceramic is characterized by flexural strength of about 120 MPa and fracture toughness of $1.6\text{--}1.8\text{ MPa}\sqrt{\text{m}}$, while lithium disilicate shows a flexural strength in the range 350–450 MPa and fracture toughness in the range $2.8\text{--}3.5\text{ MPa}\sqrt{\text{m}}$ ([Ho and Matinlinna, 2011](#)). Thanks to lithium-disilicate glass-ceramics, it is now possible to produce all-ceramic partial dentures made of three elements ([Kern et al., 2012](#)). Fluorapatite is mainly used for its chemical and structural similarity to hydroxyapatite, which provide excellent biocompatibility, besides a possible fluoride release ([Gineste et al., 1999](#)) able to stimulate new bone formation ([Rodríguez-Lorenzo and Gross, 2003](#)).

However, in spite the improvement in mechanical properties shown by the glass-ceramics, glass-containing dental materials still show poor strength in load-bearing conditions. For this reason, a different approach has been developed, in which such esthetic ceramics are used in combination with a stronger and tougher core, made of polycrystalline alumina or zirconia. In such a way, structural and optical properties are both achieved in dental restorations. Biomedical-grade alumina was introduced in the medical market (especially for orthopedics) starting from the 60's, due to its excellent biocompatibility, high hardness and wear resistance and good flexural strength (in the range 400–580 MPa) ([McEntire et al., 2015](#)). However, due to low fracture toughness ($3.3\text{--}4.2\text{ MPa}\sqrt{\text{m}}$) ([McEntire et al., 2015](#)) and poor reliability, alumina ceramics were progressively substituted by zirconia ceramics, characterized by an impressive flexural strength (700–1500 MPa, [McEntire et al., 2015](#)) and high/very high fracture toughness (in the range $4\text{--}20\text{ MPa}\sqrt{\text{m}}$, [McEntire et al., 2015](#)) as it will be deepened in Section “Monolithic Restorations: From Y-TZP to Innovative Zirconia-Based Compositions”. A different approach, but still dealing with polycrystalline core ceramics, consists on producing glass-infiltrated ceramics, still with the aim of further increasing the reliability of those dental materials. In this case, a porous core made by a polycrystalline ceramic is infiltrated by a proper glass, creating an interpenetrating structure and

providing an effective mechanism to limit crack propagation thanks to the glassy phase (Ho and Matinlinna, 2011). These ceramics are mainly used in substructures for anterior or posterior single crown and short span anterior partial dentures (Ho and Matinlinna, 2011).

In spite the several advances reached by dental ceramics over the years, the achievement of all the main requirements in a single material is still challenging. For this reason, new solutions are currently under development, and those related to all-ceramic materials and related technologies are briefly discussed in the following (Fornabaio *et al.*, 2017).

All-Ceramic Dental Materials: New Frontiers in Materials and Processing

Monolithic Restorations: From Y-TZP to Innovative Zirconia-Based Compositions

The development of layered ceramics, consisting on an esthetic ceramic applied on a polycrystalline core, presents a major issue related to chipping and delamination of the low-strength porcelain veneer as respect to the high-strength core (Silva *et al.*, 2017). The residual thermal stresses arising during cooling from high-temperature firing are the main reason for chipping and delamination phenomena (Al-Amleh *et al.*, 2014).

For this reason, monolithic restorations based on polycrystalline structural ceramics, like zirconia, were introduced (Malkondu *et al.*, 2016). The basic idea is to avoid veneering, since the monolithic material should provide both mechanical performance and esthetics. The best candidate ceramic material for this new approach is zirconia, ZrO_2 . As previously mentioned, zirconia is characterized by an exceptional flexural strength and fracture toughness, deserving the title of “ceramic steel” (Garvie *et al.*, 1975). The remarkable properties of this ceramic are mainly ascribable to the tetragonal-to-monoclinic (*t-to-m*) zirconia phase transformation. In fact, zirconia exists into three polymorphs: from room temperature to about 1170°C, the stable phase is the monoclinic one; the tetragonal structure exists between 1170°C and 2370°C, and the cubic phase above this last temperature and till the melting point (2680°C). Therefore, during cooling from the sintering temperature, a spontaneous *t-to-m* transformation occurs, which is accompanied by a significant volume expansion ($\sim 5\%$), thus leading to the failure of the ceramic pieces. In order to overcome such a problem, the high-temperature polymorphs of zirconia are stabilized by proper dopants, such as yttrium oxide (Scott, 1975). In such a way, during cooling, the high-temperature tetragonal phase can be retained at room temperature in a metastable state. Under an applied stress, metastable tetragonal grains can transform again to monoclinic ones: the consequent volume expansion gives rise to a compressive field exerted on the crack, hindering its propagation and avoiding the catastrophic failure of the ceramic. Such toughening transformation is the main mechanism responsible of the high strength and toughness of zirconia ceramics (Hannink *et al.*, 2000). Ytria-stabilized polycrystalline tetragonal zirconia (Y-TZP) started to be used as a biomedical material in the 90's, especially for orthopedic implants, to overcome the intrinsic brittleness of alumina ceramics and increase the reliability of biomedical ceramic devices (El-Ghani and Sherief, 2016). Only recently, monolithic Y-TZP was introduced in the dental market, its success again due to its outstanding mechanical properties. In spite characterized by high strength and hardness, recent investigations showed no serious damage by wear on the antagonist dental tissue (which could be either natural enamel or a ceramic material), or at least comparable to that induced by other more traditional restorative ceramics (Silva *et al.*, 2017).

Compared to the glass-based dental materials, the esthetics of polycrystalline Y-TZP is of lower quality. In order to achieve a higher translucency, the current strategies include increasing the zirconia purity and the fired density, decreasing the grain size and structural defects, or also increasing the amount of cubic zirconia. Lack of translucency in ceramics is mainly due to light scattering effects from grain boundaries and defects. Moreover, in not cubic structure, birefringence occurs, *i.e.*, the occurrence of different refractive indexes, depending to the crystallographic orientation. In order to minimize the birefringence, the grain size should be decreased below a critical value (Zhang, 2014). The addition of cubic zirconia, characterized by isotropic optical properties, is effective in increasing the translucency as well. Thanks to such strategies, it is possible now to use monolithic Y-TZP also in esthetic regions (Silva *et al.*, 2017).

However, a serious drawback affects Y-TZP materials, which is the so-called low temperature degradation (LTD), also known as *ageing* (Lughi and Sergo, 2010). When exposed to temperature body and in presence of moisture, a spontaneous *t-to-m* transformation could occur, even if not triggered by a propagating crack. Such uncontrolled transformation can lead to catastrophic effects, such as loss of strength, generation of micro-cracks or even to the failure of the device (Chevalier *et al.*, 2009). Although the LTD mechanisms are still not completely clear, the degradation mechanism seems to be favored by the presence of yttrium in the zirconia lattice (Bartolomé *et al.*, 2004) creating oxygen vacancies. In fact, in presence of moisture, OH^- groups can move from the surface to the bulk of the material through grain boundary diffusion, filling the oxygen vacancies of the zirconia lattice and destabilizing the metastable tetragonal phase (Lawson, 1995). LTD had a catastrophic effect on Y-TZP heads used in hip prostheses, leading to the premature failure of a consistent number of ceramic heads in a very short period of time (between 2000 and 2002), and causing the immediate withdrawn of zirconia balls from the orthopedic market (Lughi and Sergo, 2010). In the case of Y-TZP for monolithic restorations, the results concerning its ageing behavior are still controversial (Flinn *et al.*, 2017; Pereira *et al.*, 2016; Adabo *et al.*, 2015; Cattani-Lorente *et al.*, 2011) and deserve further investigations.

However, in order to limit or completely avoid this issue, current research is focusing on alternative zirconia dopants as well as to the development of innovative zirconia-based composites. As the undesired transformation is triggered by oxygen vacancies, the choice of alternative stabilizers, having a tetravalent cation, to substitute Zr^{4+} in the zirconia lattice is a proper strategy. Therefore,

Low-temperature degradation of different zirconia ceramics for dental applications. *Acta Biomaterialia* 8, 1213–1220.

Fig. 4 Field emission scanning electron microscope (FESEM) microstructures of Ce-TZP (left) and Ce-TZP/16vol%Al₂O₃ composite (right), both sintered at 1450°C for 1 h.

most attention is now focused on the development of CeO₂-stabilized zirconia, referred to as Ce-TZP, in which CeO₂ is normally added in the 8–12 mol% range (Tsukuma and Shimada, 1985). The improved stability towards ageing of Ce-TZP compared to Y-TZP has been already demonstrated in literature (Deville *et al.*, 2005), showing safe conditions during clinical use.

The addition of CeO₂ to a zirconia lattice induces a significant grain growth, as shown in Fig. 3 which compares the sintered microstructures of Y-TZP and Ce-TZP materials (Kohorst *et al.*, 2012). We can observe that, under proper sintering conditions, it is possible to achieve fully dense and highly homogeneous materials. However, a significant difference in grain size characterizes these two materials, since Y-TZP is characterized by an average size of 500 nm, while Ce-TZP presents a micron-sized microstructure, whose average size is 1.8 μm (Kohorst *et al.*, 2012). Moreover, grains pull-out (black arrow in Fig. 3) and some residual porosity could be observed as well.

As expected, the coarsened microstructure in Ce-TZP leads to a decrease of mechanical properties as compared to Y-TZP. In fact, the former material was characterized by a flexural strength of 495 ± 11 MPa, the latter of 1740 ± 151 MPa. However, when exposed to ageing conditions (hydrothermal treatment, at 134°C and 3 bar), Y-TZP showed a progressive and significant decrease in strength by increasing the ageing time. On the opposite, no significant strength variation in Ce-TZP was detected (Kohorst *et al.*, 2012).

In order to increase the flexural strength, many papers underline the beneficial effect of adding second-phase particles, such as alumina (Ban *et al.*, 2008). Due to the pinning effect exerted by fine-grained and homogeneously distributed Al₂O₃ particles, it is possible to retain the zirconia grain growth during sintering, and to achieve a significantly finer microstructure. Fig. 4 compares the microstructures of pure Ce-TZP (left) and of the same material added with 16 vol% Al₂O₃ (right), both sintered under the same

Fig. 5 Typical microstructure of a triphasic composite having composition Ce-TZP/16vol%Al₂O₃/16vol%SrAl₁₂O₁₉, developed by the authors and co-workers. The high density and microstructural homogeneity of phase distribution is evident in the lower-magnification image (left), while the powder morphology is evidenced in the higher-magnification image (right).

conditions (1450°C/1 h). We can observe the key role exerted by the fine-grained and homogeneously distributed Al₂O₃ particles in providing an effective retention of the zirconia grain size (Fornabaio *et al.*, 2015). Besides refining the microstructure, the addition of the hard and stiff alumina phase induces an overall enhancement of Ce-TZP mechanical properties, especially the flexural strength and the hardness. On the other hand, the *t*-to-*m* toughening transformation is hindered, leading to a decrease of the composite fracture toughness as compared to pure Ce-TZP.

For this reason, the last generation of tough and strong zirconia-based ceramics are designed as multi-phase composites, where besides Al₂O₃, a further second-phase is added, characterized by elongated or rod-like morphology, and able to further increase the material fracture toughness by additional crack deflection and crack bridging mechanisms (Cutler *et al.*, 1994; Miura *et al.*, 1994; Palmero *et al.*, 2015; Apel *et al.*, 2012; Kern, 2014). As a consequence, strong, tough and stable zirconia materials can be successfully obtained. In this field, a key role is played by the manufacturing, since in order to achieve fine and controlled microstructures in such complex composites, all processing steps – from powder synthesis to final sintering, have to be properly controlled (Palmero *et al.*, 2011, 2014). In Reveron *et al.* (2017) the fine tuning of the ceria content inside the zirconia matrix and the fine microstructural refinement achieved thanks to the addition of two kinds of second-phases, fine and rounded Al₂O₃ particles and elongated SrAl₁₂O₁₉, allowed to achieve outstanding mechanical properties. In Fig. 5, a typical microstructure of this triphasic materials, developed by the Author and co-workers in the frame of Longlife European Project “Advanced multifunctional zirconia ceramics for long-lasting implants”, grant agreement no 280741, is depicted. In the lower magnification image (left), it is possible to observe the fully dense and highly homogeneous microstructure obtained, with a perfect distribution of the all the phases in the composite materials. In the higher magnification image (right), it is possible to appreciate the different morphologies which characterize this composite materials, with both fine-grained round Al₂O₃ particles and rod-like SrAl₁₂O₁₉ particles, both homogeneously embedded in a fine-grained CE-TZP matrix.

In fact, the material was characterized by very high flexural strength (> 1 GPa) and fracture toughness (> 10 MPa√m), besides high stability against ageing. Even more, due to transformation toughening, the material showed a certain plasticity before failure. Such metal-like behavior was responsible of the exceptional Weibull modulus ($m \cong 60$) which characterized this material. High mechanical performance, *in vivo* stability and reliability make this innovative composite suitable for biomedical applications, in particular way in dental restoration. However, Ce-TZP does not present translucency and the presence of ceria imparts a certain yellowish coloration, making this solution at the moment suitable only for implants and for restorations for non-esthetic regions.

Functionally Graded Ceramics

In search of proper esthetics besides good mechanical properties, a new strategy implies the development of functionally graded materials (FGM), which can be considered an evolution of layered ceramics and glass-infiltrated ceramics (Zhang *et al.*, 2010, 2012). The concept behind FGM is to provide a gradual change in the structure or in the compositions, and thus in the material functionality. In order to join mechanical performance and esthetics, Zhang and Kim (2009) developed an Y-TZP/glass graded structure. The glass composition was designed in order to match the coefficient of thermal expansion (CTE) of Y-TZP. In particular way, it consisted on a silica-alumina glass containing K, Na, Ca and Tb oxides in proper concentration. To produce the graded structure, Y-TZP was pre-sintered in order to create a porous template for the glass. The top and bottom surfaces of the porous pellet were covered with powdered glass, and the system was heated at 1450°C/2 h, in order to have infiltration and densification at the same time. The process succeeded in the development of the desired graded structure, as shown in Fig. 6: on both surfaces a residual glass layer was detected (a), while moving toward the inner part a compositional gradation was observed, with a progressive decrease of the glassy phase and an increase in the zirconia amount, up to the achievement of a dense Y-TZP core (b). No phase transformation was observed after infiltration and sintering: in fact, tetragonal zirconia was the only crystalline phase detected in the final material. As a consequence of composition gradual change, a progressive variation of mechanical properties

Fig. 6 Scanning electron microscope (SEM) images showing cross-section (polished) glass-infiltrated Y-TZP materials, after sintering at $1450^{\circ}\text{C}/2\text{ h}$. (a) Low magnification image showing the presence of residual glass layer ($\sim 50\text{ }\mu\text{m}$ thick) at both the top and bottom surfaces. (b) Higher magnification image of the inserts (white boxes) of (a), still showing the outer surface residual glass layer (black), which gradually decrease in the graded glass-zirconia layer, and the dense Y-TZP core. Digital photographs showing veneering surfaces of a “traditional” (c) and glass-infiltrated (d) three-unit Y-TZP framework, both sintered at $1450^{\circ}\text{C}/2\text{ h}$. Reprinted with permission from Zhang, Y., Kim, J.-W., 2009. Graded structures for damage resistant and aesthetic all-ceramic restorations. *Dental Materials* 25, 781–790.

was achieved as well: in particular way, both the elastic modulus and the hardness showed the lowest values in correspondence to the external residual glass. However, by moving from the surface towards the inner core, both increased in a progressive way. In the core, the elastic modulus and hardness were 3.5 and 2.1 times those of the glassy phase. The digital photographs in Fig. 5 show the appearance of glass-infiltrated (c) and monolithic (d) Y-TZP materials, both sintered at $1450^{\circ}\text{C}/2\text{ h}$. In the former case, we can observe that the material is characterized by proper optical properties, in term of translucency and shade, while the un-filtrated material shows a white and completely opaque appearance.

The FGM approach was also exploited by Fabris *et al.* (2017) to overcome the issue related to the generation of thermal residual stresses generated within layered dental ceramics. In the traditional technology, the external glassy veneer is directly fired onto the polycrystalline core, at high temperature. During cooling, significant thermal residual stresses are created, due to the CTE mismatch between the core and the external layer. In addition, the differences in elastic modulus between the same two layers can lead to stress generation during the masticatory activity, thus creating microcracks. Such issues are the major responsible of catastrophic failure of dental ceramics, as well of chipping of the veneer layer (Fabris *et al.*, 2017). Through mathematic models, the residual stresses in three different structures were calculated. The first was a traditional bilayer structure (glass veneer – polycrystalline ceramic core); the second was a trilayer structure, with an additional layer between veneer and core having an intermediate composition; the last one was a FGM in which a graded interlayer was considered between veneer and core. As expected, the bilayer system was characterized by the highest thermal residual stress, while both multilayer structures showed significantly lower stress.

FGM seems to be an effective strategy to avoid delamination and fracture of the layered ceramics, and to improve their overall mechanical properties and esthetics. Besides simulations (Fabris *et al.*, 2017) and laboratory-scale developments, efforts are in course to bring this technology to the market. An example is provided by Abu Kasim *et al.* (2013) who patented three types of multilayered composite materials based on zirconia, alumina, hydroxyapatite and titanium, to develop newly designed functionally graded dental posts.

Le Ferrand *et al.* (2015) proposed a very innovative method to develop functionally graded materials, characterized by a complex architecture, able to better mimic the natural living tissues. The method is based on magnetically assisted slip casting. As in traditional slip casting, a ceramic suspension is poured into a porous gypsum mold of a pre-defined and even complex geometry. Thanks to capillary forces, the liquid is extracted by the porous mold, and a cake is formed at its surface. By progressively changing the composition of the ceramic slurry cast into the gypsum mold, it is possible to achieve a compositional gradation. Even more, in this work, the ceramic slurry was added with alumina platelets, previously functionalized by paramagnetic Fe_3O_4 nanoparticles. Thanks to the application of a magnetic field during the slip casting process, it was possible to orient the platelets, and achieve the desired textured microstructure. This approach has been applied by the authors to mimic the structure of a human molar. For the dentin tissue, the suspension was made by a mixture of isotropic alumina particles and functionalized alumina

platelets; for the enamel, the isotropic alumina particles were partially replaced by silica particles. In such a way, during sintering, silica particles generated a glassy phase which filled the residual porosity in the alumina structure, and provided a denser and harder external layer. In addition, by applying a proper magnetic field, it was possible to orient the alumina platelets, and precisely with a perpendicular orientation to the external surface in the enamel-like layer, and parallel to the same surface in the dentin-like layer.

Innovative Manufacturing

The use of CAD-CAM (computer-aided design/computer-aided manufacturing) systems in the dental market is now a well consolidated process. It is a kind of subtractive process, in which material is progressively removed from a blank or a green part, according to a defined design. Its success is mainly due to the fact that the process is less time-consuming as respect to traditional manufacturing methods: with CAD-CAM process, in fact, it is possible to use high-speed grinding to shape dental crowns. Moreover, it allows a perfect design of the digital dental restoration, characterized by accuracy and precision and customized on the patient's clinical requirement. Still important, prediction of the final outcome is possible as well. In spite of being used for almost 30 years, a continuous evolution of the process and systems occurs, in terms of both equipment and processable materials, moving from traditional porcelain to esthetic ceramics, polycrystalline ceramics and composites (Silva *et al.*, 2017). The major drawback of this manufacturing method is the huge amount of waste produced, which could reach 90% of the prefabricated block (Silva *et al.*, 2017). Therefore, alternative processing methods have been developed, to provide a more efficient and sustainable production of dental restorations. In particular way, new additive methods have been developed and some of them adapted to the dental materials manufacturing. In spite of different 3D printing processes are nowadays available on the market, few technology allows the fabrication of all-ceramic materials, and precisely inkjet printing (also known as robocasting) and stereolithography.

An example is provided by the work of Ebert *et al.* (2009) who used direct inkjet printing to develop zirconia dental materials. The ink was prepared starting from a boehmite sol, to which zirconia nanoparticles were added, besides dispersants. The slurry was used to fill the standard cartridge of a modified commercial printer and to develop the 3D structure through layer by layer processing. The printed material was dried and further sintered at 1450°C/2.5 h, resulting in a high final density (96.9% of the theoretical density) and a quite homogeneous microstructure. Flexural strength and fracture toughness were 763 MPa and 6.7 MPa√m, respectively, while the Weibull modulus was 3.5. The low reliability of the developed parts was mainly imputed to the presence of large defects induced during the printing process.

In stereolithography process, a ceramic powder (up to 50 vol%) is mixed with a low-viscosity UV-curable monomer, to get the feedstock paste. During the process, reticulation of the polymer occurs, thus allowing to build 3D structures made of "green" ceramic layers. A proper thermal debinding is then required to remove the organic fraction, followed by high-temperature sintering to consolidate the ceramic structure (Lian *et al.*, 2018). By exploiting this technology, Dehurtevent *et al.* (2017) developed alumina dental ceramics, by investigating the role of the Al₂O₃ particle size (either sub-micrometric and micrometric) and solid loading in the monomer. The best results were achieved by using the larger-size particles, at the highest solid loading, yielding density and flexural strength comparable to materials obtained by traditional subtractive method. Digital images of the dental materials produced are presented in Fig. 7. In spite of the results achieved suggest that stereolithography could be an evaluable alternative the

Fig. 7 Digital images of stereolithography-manufactured alumina dental crown framework: external (A) and internal (B) views. Crown framework in place on an all-ceramic crown preparation (C). Reprinted from Dehurtevent, M., Robberecht, L., Hornez, J.-C., *et al.*, 2017. Stereolithography: A new method for processing dental ceramics by additive computer-aided manufacturing. *Dental Materials* 33, 477–485, with permission.

standard procedures, the authors underlined the need of more studies on the subject. The major drawback consists on the significant shrinkage experienced by the materials during debinding and sintering. Moreover, the authors observed a not-isotropic shrinkage, unlike subtractive-processed materials. Such anisotropy, besides the presence of residual uncured monomers and unsuitable curing strategies, may induce distortion's and cracks in the pieces, particularly when complex-shapes have to be processed.

Conclusions and Perspectives

The use of ceramics in the dental market is continuously increasing, as they outperform other class of materials mainly in terms of biocompatibility, chemical stability and key mechanical properties such as hardness and wear resistance. However, challenges remain in the development of all-ceramic dental restoration which could satisfy both mechanical performance and esthetics in long-lasting solutions. In fact, the traditional approach of applying an esthetic, predominantly glassy layer (the so-called veneer) on the surface of a polycrystalline structural ceramic show chipping and delamination and major drawbacks. For this reason, new solutions, materials and technology are currently under development. The directions for current and future research are depicted in this contributions, still restricting the discussion to all-ceramics solutions.

In this frame, two main strategies are being followed. The former approach focuses on the design and development of innovative compositions for all-ceramic monolithic restorations. Here in fact, most attention is nowadays focused on monolithic yttria-stabilized zirconia, which presents exceptional flexural strength, high fracture toughness and good esthetics, therefore suitable for implants and prosthesis in the posterior part of the mouth, subjected to the highest stresses. However, the risk of *in-vivo* degradation is leading the research to find innovative solutions, in terms of zirconia dopants, second-phases, and manufacturing methods able to provide reliable and long-lasting ceramics. The second approach, which intends to mimic the natural dental tissue architecture, focuses on the design and development of functionally graded ceramics. This approach is being exploited with the main purpose of producing a glass-ceramic compositionally graded structure, to avoid neat interfaces between the veneer and ceramic core, and therefore limit chipping and delimitation issues.

Furthermore, some very recent papers demonstrate the feasibility of using additive manufacturing techniques as possible alternative to subtractive methods, such the CAD-CAM based standard process. If successful, these methods could lead to higher productivity and lower waste, as well as the possibility to manufacture complex-shape bridges or other dental components, which are currently difficult to produce with other techniques.

Oxide Ceramics for Biomedical Applications

Corrado Piconi and Anna Tampieri, Institute for the Science and Technology of Ceramics, National Research Council, Faenza, Italy

© 2021 Elsevier Inc. All rights reserved.

Introduction

The biomedical applications of oxide ceramics today are related to two main field:

- (1) Orthopedic joint replacements, where oxide ceramics are used for the manufacture of components of the bearing, i.e., ball heads and inserts for hip replacements, femoral (condylar) component for knee replacements, glenoid head in shoulder replacements, etc.
- (2) Dentistry, where oxides are used in dental implants either in the production of crown, bridges and fixed partial dentures obtained by CAD/CAM from ceramic blanks.

The use of oxide ceramics in orthopedic joint replacements for several peculiar characteristics of these materials that can be summarized as follows:

- (1) Biological safety of the material, of its debris and of its degradation products, if any;
- (2) Chemical stability in the long term: absence of corrosion/ion release;
- (3) Suitability of the mechanical properties to assure the component expected behavior;
- (4) Physical stability: very low wear, absence of swelling, stiffness under load;
- (5) High surface finish achievable;
- (6) Scratching resistant surface;
- (7) Suitability for the geometrical design of the components;
- (8) Workability by common mechanical tooling;
- (9) Contained production costs.

The oxide ceramics in use today in joint replacements are aluminum oxide (alumina, α -Al₂O₃, corundum), alumina matrix composites (AMCs) and stabilized zirconium dioxide (zirconia, YTZP). So far, alumina has been replaced progressively by alumina-zirconia composites in orthopedics because of the better mechanical behavior of these ceramics that allow higher flexibility in device design joined to higher reliability of ceramic components, while zirconia (YTZP) and alumina-toughened zirconia (ATZ) are today the oxide of reference in dentistry.

Alumina was the first oxide introduced in clinical use. In orthopedics, it became the “ceramic” and in scientific papers the use of the term “ceramic” without any other specification to indicate alumina is accepted. Nevertheless, this may result confusing because of the many ceramics that are, have been used in clinics or are under development for use in joint replacements besides alumina (e.g., Y-TZP, Mg-PSZ, Si₃N₄, ZTA, ATZ, etc).

A few number companies are manufacturing ball heads for THRs worldwide. While some of them are among the pioneers in this field and operate in the orthopedics market since a long, other are newcomers attracted by the growing diffusion of ceramics in arthroplasty. The Medical Products Division of CeramTec GmbH (Plochingen, Germany) deliver about 80% of the worldwide demand. For a detailed description, the reader may refer to a former work of the senior author (Piconi, 2017).

Although the main use of oxide ceramics is in components of joint replacement bearings, new applications are emerging in dentistry (Piconi *et al.*, 2008, 2014; Piconi and Sprio, 2018). In dentistry, zirconia (Y-TZP) is today the oxide ceramic of reference for the production of load bearing devices.

The Development of Oxide Ceramics in Biomedical Applications

It is known that the first patent on the use of an oxide ceramic (alumina) as a biomaterial is made in a 1932 patent by Rock (1933), but it had no practical consequences. In the early times, the development of oxide ceramics in biomedical applications had as reference bone substitutes, but since the studies of Boutin *et al.*, it was targeted on the components of bearings for Total Hip Replacements (THRs).

First clinical use of alumina was in Cerosium, a material developed by Smith in the USA. It was a porous (65 vol%) aluminosilicate loaded by epoxy resin, intended to be implanted to replace large defects on the long bones (Smith, 1992).

However, the real start took place about the mid-1960, when the company Degussa GmbH (Düsseldorf, Germany) introduced into the market its powder Degussit Al23, the first high-purity, high-alumina ceramic precursor that allowed obtaining ceramic parts suitable for medical applications within the human body by high temperature sintering.

Using Degussit Al23 Sandhaus, a Swiss dentist, developed its CBS dental implant, a device that had pretty good clinical outcomes (Sandhaus, 1969). It can be hypothesized that information about this device stimulated the interest of Dr. Pierre Boutin, an orthopedic surgeon with practice in Pau, France. With the help of one of his patient who was a top manager in a ceramic workshop nearby Dr. Boutin developed in 1970 the first ceramic-ceramic bearing for Total Hip Replacement (THR) (Boutin, 1972).

Shortly after, researchers in Keramishe Werk Hermsdorf (KWH, Hermsdorf, Germany) launched the development of alumina unicompartimental tibial plateau replacements (Glien, 1980). These devices that are the first ceramic devices used in the knee joint, were implanted by prof. Langer in Jena (Langer and Blumentritt, 1987; Langer, 2002). In the same years, prof. Hironobu Oonishi, a pioneer in the development of ceramic devices, launched the development of the first Total Knee Replacement (TKR). This device (the so-called KOM-1) – made by the company Kyocera (Kyoto, Japan) – were formed by an alumina femoral component articulating on a polyethylene insert hosted on an alumina tibial plateau, and were implanted cementless in 134 patients. (Oonishi, 1990, 2006) Kyocera developed also unicompartimental knee replacements that showed high success rate at controls made at an average 42 months after surgery (24–68 months) (Atsui *et al.*, 1997).

Since then several other TKR design based on alumina were developed in Japan, such as the Low Friction Anatomical (LFA-1), the Yokohama Medical Ceramic Knee (YMCK), the Bisurface knee replacement, and the Kyoto Ceramics-1 (KC-1). (Solarino *et al.*, 2017).

There were several failure in the first series of Boutin's implants. In these devices both the alumina cup, both the metallic stem were fixed to the host bone by cement, while the ceramic ball head was fixed by epoxy glue to a cylindrical trunnion at the extremity of the stem. Both the bone cementation both the glue degradation were at the origin of the failures.

The research program launched in Germany to develop alumina ceramic components for THR applications had as reference two key concepts:

- (1) To achieve direct-to-bone fixation both of the cup and the stem (although some version of the implants were designed for cement fixation too);
- (2) To connect the ceramic head to the stem by a Morse-like taper connection.

Especially relevant is the introduction of the Morse Taper connection, which marked a milestone in arthroplasty, opening the way to modularity in joint replacements (Hernigou *et al.*, 2013).

The clinical results from the early alumina-alumina ceramic designs proved to be mixed at best. Because of the design of some implants and of the poor quality of some materials, alumina ball-heads experienced an unacceptable rate of failure on the first years of clinical use (Piconi *et al.*, 1999).

Nevertheless, this early clinical experience with alumina ceramic component in THR allowed assessing that:

- (1) The wear rate of these early alumina ceramic bearings was very low in comparison with metal-polyethylene bearings (2.6 $\mu\text{m}/\text{year}$ for the cup; 5.4 $\mu\text{m}/\text{year}$ for the head);
- (2) The application of these components in younger patients reduced complications related to aseptic loosening of the components thereby reducing drastically the incidence of clinical complications (Piconi and Streicher, 2013).

Due to implant failures, several manufacturers that undertook the production of alumina ceramics for medical applications withdrew from the market in the early 1980s. The ones committed to pursue the development of ceramic joint replacements started a process aimed to:

- (1) Increase the mechanical properties of the products increasing density and decreasing the grain size,
- (2) Develop tough ceramics.

The first approach led about 1995 to the present generation of high purity alumina, obtained by selected precursors by a manufacturing process carried out in the framework of a Total Quality System. Technological improvements (Hot Isostatic Pressing, laser marking, and proof testing) allowed obtaining alumina ceramics with bending strength about double the one of the early materials (Piconi and Streicher, 2013).

The other approach was based on the discovery of the phase transformation toughening in partially stabilized zirconia (PSZ) by Garvie *et al.* (1975) and shortly after in tetragonal zirconia polycrystal (TZP) by Gupta *et al.* (1977).

The development of ball heads for THR by Yttria-stabilized tetragonal zirconia polycrystal (Y-TZP) in clinical applications is due to the work of the team lead by two French scientists, Bernard Calés and Pascal Christel. Fostered by the company Ceramiques Techniques Desmarquest, (Everux, France) (Christel *et al.*, 1988; Calés and Stefani, 1995; Piconi and Maccauro, 1999).

YTZP allowed a larger flexibility in design of ceramic components for joint replacement overcoming the limitations due to the mechanical properties of Alumina. Nevertheless, YTZP is a complex material that may exhibit different properties and varying stability depending on processing and on the conditions of use. This led to mixed performance records in clinics (Piconi *et al.*, 2007). Finally, the worldwide product withdrawal of zirconia ball heads on 2001, although interesting only two lots of a single manufacturer, led to the practical abandonment of YTZP in joint replacement (Piconi *et al.*, 2006).

This created a technological gap, leaving unattended the demand for several innovative devices made out oxide ceramics, whose design needs a material with mechanical behavior improved with respect to alumina. The development of the composite ceramic known by the tradename BIOLOX®delta gave a new momentum to the whole field (Burger, 1997). This composite is constituted by an alumina matrix containing a homogeneous dispersion of fine zirconia grains and of zirconium aluminate platelets. It is today the reference material in ceramic joint replacements. In addition, it has allowed the development of several new ceramic devices, and opened the way to a new class of oxide ceramic composites now under development worldwide.

Alumina

Chemical-Physical and Mechanical Properties

Among the seven forms of alumina known, only alpha- alumina, or corundum, is suitable for use as bio- material due to its high stability. Alpha-alumina (known also as corundum, or emery if containing impurities), is forming in nature several gemstones, e.g., ruby red in color for the presence of chromium, or sapphire, blue in color due to titanium. Alpha-alumina is aluminum metal in its highest oxidative state: then, no more oxidative reactions are possible, the chemical and physical stability of the material being the maximum achievable. The strong ionic and covalent chemical bonds between Al^{3+} and O^{2-} are giving to the material an high melting point, hardness, and resistance to the attack of strong inorganic acids, like e.g., orthophosphoric, or hydrofluoric acid (Piconi, 2011).

Alpha-alumina has a crystal structure, formed by h.c.p. layers of oxygen atoms, with two-thirds of octahedral sites occupied by aluminum atoms. The surface layer of O^{2-} anions allow the chemisorption on the surface of OH^+ groups, then the bonding of water molecules or proteins. In other words, the surface has an high wettability, higher e.g., of several metallic alloys, allowing to establish a fluid film at the interface in the joints of arthroprostheses' bearings using ceramic components. Joined to the high hardness of alumina (2000–2200 GPa), the wettability of the surface is making this ceramic the ideal material for the components of the arthroprostheses joints (Oonishi *et al.*, 1999; Rieger, 2001; Piconi, 2011).

To achieve the mechanical properties required by the specifications of a medical-grade alumina (ISO, 6474), ceramics must have almost no porosity, very high density, fine grain size, and high grain size homogeneity. Poor control of the micro- structural properties, or a level of impurities of such high concentration that it could lower the stability of the material in vivo (Walter, 1992) were probably the initiators of the failures that were observed in the first years of clinical use of alumina. Because of the use of starting materials of better purity, developments in ceramic processing, and the introduction of proof testing in quality control of ball-heads these failures have been eliminated. Coupled with the use of high- purity powder, the introduction into the manufacturing process of hot isostatic pressing (e.g., 1400°C, 1000 bar) after sintering of the ball-heads allows ceramics with a typical grain size below 2 μm and a further reduction in porosity to be obtained (Richter *et al.*, 1998). The most evident effect of such improvements is the increase in mechanical properties of medical-grade alumina, e.g., the bending strength that was increased in the period 1970–90 from 400 MPa to about 630 MPa. The introduction of proof testing in final control allows the elimination of all the components presenting defects undetectable by conventional methods. In a proof test, ball-heads are submitted for a short time to loads several times the maximum expected in service. All the components that fail below a preset threshold stress level are eliminated. The proof stress levels and hold time are functions of the expected life- time of the component, and are identified on the basis fracture mechanics theory. (Piconi, 2011).

Alumina is sensitive to cyclic loading, as under these conditions flaws (e.g., residual pores, large grain boundaries) may grow and reach a critical size. In the presence of water, the water molecules that permeate the material through the open porosity can enhance the growth of subcritical cracks in alumina (Dörre and Hubner, 1984). During production of materials that have to operate in the physiological environment, it is then very important to obtain a high-density, pore- free structure. The interaction of water with the impurities or the additives plays an important role in stability. To limit grain growth during sintering, it is common to introduce in the material small quantities of MgO (<0.1 mol%) as a sintering aid. Care must be taken in controlling the amount of MgO , as excess may induce the formation of foreign phases in Al_2O_3 , and to control the concentration of impurities like SiO_2 and NaO that can form leachable glassy phases at grain boundaries. Also, the reaction between CaO impurities and water can cause fatigue failure of alumina components (Dörre and Hubner, 1984; Rieger, 2001; Walter, 1992).

Alumina Biocompatibility

Extraction procedures performed by media suitable for cell culture have shown the absence of release from alumina, and a very low cellular reactivity. Alumina has shown a very low degree of cell stimulation towards macrophage and lymphocytes: macrophages incorporating alumina particles still exhibit an excellent chemotactic response, showing the low toxicity of ceramic particles.

When implanted in soft tissues, alumina ceramics (disks, cylinders) are surrounded by a layer of connective tissue. This pseudomembrane transforms progressively in a layer of connective tissue. After the implant of alumina ceramics in bone in nonloaded conditions, fast bone formation is observed in close contact with the ceramic implant without fibrous interposition, the implant remaining stable in time due to surface texture, which is penetrated by cell dendrites. There is no chemical bonding: alumina is a “nearly inert” material. A proteoglycan layer is present at the bone–biomaterial interface. Micromotions of the implant increase the thickness of the fibrous capsule. Bone apposition at the interface is enhanced by the stresses due to loading.

The tissue reaction to the injection of alumina particles in several animal sites is characterized by the presence of granulocytes and lymphocytes in a quantity lower than the ones observed after the injection of metals. In comparison to metal and polyethylene, alumina elicits the weakest tissue response: it has been noted that alumina particles do not induce the fibrosis observed after injection of polymers or metals.

The carcinogenic reaction observed in long-term experiments (3.5 years) after the implant of alumina ceramics appears nonspecific and related more to surface geometry than to any other reaction. No carcinogenic reaction is observed after the injection subcutaneous of alumina powder in Sprague–Dawley rats (Dörre and Hubner, 1984; Christel *et al.*, 1988; Gross *et al.*, 1988; Christel, 1992; Li and Hastings, 1998).

Wear of Alumina

The hardness of α -alumina is in the range 2000–2200 HV. The high hardness of alumina implies the low wear of components of the joint, and high resistance to scratching. By diamond polishing it is possible to obtain a very fine surface finish: the typical surface of ball-heads is characterized by $R_a = 0.02 \mu\text{m}$, $R_t = 0.5 \mu\text{m}$. Coupled with a very fine surface finish, this contributes to lowering the risk of abrasive wear due to surface defects of the ball-head (Rieger, 2001).

In hip simulators tests, alumina has shown a volume wear of 1/2000 that of UHMWPE. The clinical wear of alumina THR bearings has proved to be lower than that of bearings using metal ball-heads. In alumina–alumina joints it has been observed that the wear and friction decreases with time: this is due to the formation of a double layer of water and carboxylic acids chemisorbed on the surface of alumina ceramics in vivo. The stability of this layer during the service of the joint depends on the sphericity of the components (typical sphericity deviation $\pm 0.2 \mu\text{m}$), and on the clearance existing between the ball-head and the socket. It should be noted that the ceramic particulate due to wear has proved to be very well tolerated by the organism: local and systemic reactions to ceramic wear debris are reduced, in comparison to those observed in the presence of metal and UHMWPE debris (Böhler *et al.*, 1999; Fischer *et al.*, 1999; Fischer *et al.*, 2006).

Zirconia

The introduction in arthroplasty of zirconia was made to exploit the toughness of this material, called by its discoverers a “ceramic steel” (Garvie *et al.*, 1975). The attention was initially devoted to Partially Stabilized Zirconia (PSZ). Several PSZs have been tested as ceramic biomaterials, especially Mg-PSZ, which biocompatibility has been extensively tested in vitro and in vivo with favorable results. Nevertheless, most of the development in arthroplasty shifted towards Yttria-stabilized Tetragonal Zirconia Polycrystal (Y-TZP) (Gupta *et al.*, 1977) than become the standard material for clinical applications, whose characteristics identified by the standard ISO 13356.

Namely, Mg-PSZ has some drawbacks relevant to biomedical applications. Mg-PSZ is characterized by grain sizes in the range 30–40 μm and by residual porosity. This can negatively influence the wear rate of UHMWPE sockets that are coupled with zirconia ball-heads. In addition, the complexity of the thermal cycle and the higher sintering temperature of Mg-PSZ, which is higher than that of Y-TZP (1800°C versus 1400°C), has to be taken into account, as it may constitute a technologic drawback (Calés and Stefani, 1995; Piconi and Maccauro, 1999).

Due to the advantages of Y-TZP over alpha-alumina many manufacturers worldwide introduced zirconia components into the market, with variable quality. More than 600,000 Y-TZP ball head for THR were sold by the year 2001 when took place the worldwide withdrawal of the products made by Saint Gobain – Advanced Ceramics Desmarquest who was the main zirconia heads manufacturer. The withdrawal was issued following the unexpected high rate of fracture that took place in two ball head batches processed by the new tunnel furnace introduced in the production line to increase its throughput (Piconi *et al.*, 2006). This event created a lack of confidence in zirconia ball heads whose outcomes in the clinical setting – as shown by the analysis of the literature (Piconi *et al.*, 2007) – had been mixed at the best. Moreover, the low thermal conductivity of zirconia (about one tenth the one of alumina), (see Table 1) joined to its relatively low hardness does not allow the manufacture of ceramic-ceramic bearings. For all these reasons today zirconia has been almost abandoned in orthopedics. The use of Y-TZP is limited to one Total Knee Replacement (TKR) in clinical use in Japan, while Magnesia-Partially Stabilized Zirconia (Mg-PSZ) is used in some niche products. On the other hand, Y-TZP has found a wide field of application in dentistry, as reported elsewhere in this text (Piconi *et al.*, 2014).

Chemical-Physical and Mechanical Properties

Zirconia is a well-known polymorph that occurs in three forms: monoclinic (M), cubic (C), and tetragonal (T). Pure zirconia is monoclinic at room temperature, and is stable up to 1170°C. Above this temperature it transforms into the tetragonal and then into the cubic phase at 2370°C. On cooling, a T–M transformation takes place in a temperature range of about 100°C below

Table 1 Selected behavior of oxide ceramics currently used in joint replacements

Property	Alumina (1970s)	Y-TZP	Mg-PSZ	Alumina (BIOLOX [®] forte)	BIOLOX [®] delta AMC	Ceramys [®] ATZ
Al ₂ O ₃ content (vol%)	99.1–99.6	–	–	> 99.8	80	20
ZrO ₂ content (vol%)	–	> 99	> 99	–	17	80
Density (g/cm ³)	3.90–3.95	6.02	5.5	3.97	4.37	5.51
Thermal Conductivity (W/mK)	30	2.5	3	–	–	–
Hardness (HV)	1800	1200	1500	2000	1760	1500
Flexural strength (MPa)	> 300	1000	400–650	630	1390	1039
Fracture Toughness (MPa m ^{1/2})	3.5	4.5	12.5	4.5	> 6	7.4
Young Modulus (GPa)	380	210	210	407	–	–

1070°C, associated with a volume expansion of some 3%–4%. Stresses generated by the expansion originate cracks in pure zirconia ceramics that, after sintering in the range 1500–1700°C, break into pieces during cooling to room temperature. The addition of “stabilizing” oxides, like CaO, MgO, CeO₂, and Y₂O₃, to pure zirconia allows the generation of a multiphase material known as partially stabilized zirconia (PSZ), which has a microstructure at room temperature formed by cubic zirconia containing monoclinic and tetragonal zirconia precipitates as minor phase. The homogeneous and fine distribution of the tetragonal phase within the cubic matrix improves the mechanical strength of PSZ, as the precipitates are able to transform to monoclinic when the constraint exerted on them by the matrix is relieved, i.e., by a crack advancing in the material. An enhancement in toughness is obtained, because the energy associated with crack propagation is dissipated both in the T–M transformation and in overcoming the compression stresses due to the volume expansion. In this case, the stress field associated with expansion due to the phase transformation acts in opposition to the stress field that promotes the crack propagation. The development of tetragonal metastable precipitates may be obtained by the addition of some 8 mol% of MgO to ZrO₂. This allows the formation of a fully cubic microstructure at 1800°C, and the nucleation within the matrix of a tetragonal metastable phase during controlled cooling and aging.

PSZ can also be obtained in the ZrO₂–Y₂O₃ system. However, the main interest in using yttria as a stabilizing oxide is due to the fact that in this system it is also possible to obtain ceramics formed by tetragonal grains at room temperature, called Yttria-stabilized Tetragonal Zirconia Polycrystals (YTZPs).

YTZP materials, containing some 2–3 mol% Y₂O₃, are almost completely constituted by tetragonal grains some hundreds of nanometers in size (less than 0.5 µm), the balance being some cubic phase. The fraction of tetragonal phase retained at room temperature is dependent on the size of grains, on the yttria content, and on the constraint exerted on them by the matrix. The mechanical properties of YTZP ceramics depend on such parameters.

It is very important in YTZP materials to consider the metastable nature of the tetragonal grains. A critical grain size exists, depending the yttria concentration, above which spontaneous T–M transformation of grains takes place, whereas this transformation would be inhibited in a too fine grained structure. Special attention must be devoted to avoid the presence of silica in zirconia ceramics that are to be used as biomaterials. Silica is sometimes used as a sintering additive to limit grain growth and to achieve full density at temperatures lower than 1500°C. SiO₂ and Al₂O₃ may be introduced also during powder processing before firing. The formation of aluminosilicate glasses in the grain boundaries may deplete the concentration of the stabilizing oxide Y₂O₃ in the grains, leading to a loss of stability of the tetragonal phase.

In Mg-PSZ magnesium silicates like enstatite (MgSiO₃) and forsterite (Mg₂SiO₄) may form at grain boundaries, lowering the MgO content in the grains and promoting the formation of monoclinic phase. The leaching of the glassy phase in wet environments adds a further factor in depleting the stability of the material.

Radioactive impurities in zirconia

The ores that are used for the production of the chemicals used in the powder production are associated to Uranium (²³⁸U), thorium (²³²Th) and the nuclides of their decay chains. Especially uranium and zirconia have a wide miscibility interval (International Atomic Energy Agency, 2007). These radioactive nuclides can be contained only as traces in the high purity powders that are used for the production of medical grade YTZPs (Bavbek *et al.*, 2014). The issue of zirconia radioactivity was raised about 1990, by the papers of Hopf, *et al.* that observed very high contents of radioactive isotopes in zirconia powders used as radiopacifiers in bone cements, quite different from the one suitable for fine ceramics (Hopf *et al.*, 1989, 1990). Nevertheless, these papers raised the attention on the issue of zirconia radioactivity, although measures performed on the ball heads for hip replacements were showing specific activities lower than 10 Bq/Kg, then much lower than the one of the human body (about 50 Bq/Kg) (Calès and Peille, 1990; Cieur *et al.*, 1992).

The gamma activity of the powders used in the production of YTZP ceramics zirconia was object of an extensive screening in view of their use as precursors of ceramic biomaterials. The variability of the content in gamma emitters among the different powders on the market was put in evidence (Capannesi *et al.*, 1992) as well as the effectiveness of the processes used for the purification of zirconium chemicals leading to in high purity materials with the specific activity lower than the one of human body (Piconi and Casarci, 2000). In addition, Tests performed in zirconia samples are demonstrating that doses of ionizing energy due to the prolonged use of the zirconia components are below that limits stated by the International Commission on Radiological Protection (Porstendörfer *et al.*, 1996).

Stability in Zirconia Ceramics

The metastability of the tetragonal phase that is the key of the interesting mechanical properties of zirconia is also the origin of its main drawback. In wet environments zirconia ceramics undergo the spontaneous transformation of the metastable tetragonal phase into monoclinic. The transformation, which starts on the surface and progresses into the material bulk, decreases the density of the material, and induces micro- and macrocracking. As the phase transformation progresses, one may observe the reduction in strength and toughness of the ceramic.

None of the models proposed to explain comprehensively the spontaneous T–M transformation in YTZP (Lawson, 1995; Chevalier *et al.*, 2007; Lughì and Sergo, 2010). The reaction of water with yttria to form Y(OH)₃ scavenging the stabilizer from Y-TZP grains is the mechanism was proposed by Lange *et al.* (1986) while Yoshimura *et al.* (1987) proposed a model based on a

cascade of events started by the reaction of water with Zr-O chemical bonds, leading to t-m transformation. The most recent theory, proposed by *Chevalier et al. (2009)* takes into account the reaction between O_2^- from water dissociation and oxygen vacancies in the YTZP lattice as origin of the LTD.

It is worthwhile noting that the rate of strength degradation is not the same for all TZP ceramics. Reduction in grain size and/or increase in concentration of stabilizing oxide decrease the transformation rate. Moreover, internal residual stresses, flaw population and distribution play a relevant role on this behavior. As the extent of strength degradation of YTZPs in wet environments depends on material microstructure, it can be controlled by choice of the material manufacturing process and by the precursors selected for ceramic manufacture. This makes the stability of YTZPs a characteristic peculiar to each material and of its manufacturing technology (*Chevalier et al., 2009*).

The lack of stability in wet environments may affect not only the mechanical properties of zirconia ceramics, but also the wear of UHMWPE sockets that are usually coupled to zirconia ball-heads, because of the increase in roughness that take place at the material surface. The design of precursors (e.g., yttria coating of zirconia grains) can limit this problem as well as the use of small quantities of alumina as an additive (*Lawson, 1995; Piconi et al., 1997, 1998; Palmero et al., 2014*).

Zirconia Biocompatibility

Zirconia has proved to be biologically safe in the cytotoxicity and cytocompatibility tests performed in vitro using fibroblasts 3T3 and L929, human lymphocytes, human osteoblasts, HUVEC, and macrophages (*Piconi and Maccauro, 1999; Piconi et al., 2014*).

The results of in vivo tests show the absence of local or systemic toxic effects after the implantation of zirconia ceramics, in spite of the differences among materials, shape of samples, site of implantation, and evaluation method selected. Samples have been implanted for different times into muscles or bone of different animals, as well as after powder injection in mice. During tests, especially in the early postoperative phase, connective tissue is frequently observed at the bone-ceramic interface.

Carcinogenicity and teratogenicity has been carefully studied in medical grade zirconia because high radioactivity levels were observed in some experimental zirconia ceramics in the late 1980s. This originated rumors about risks in using zirconia in medical devices, but it has been demonstrated that the precursors of medical-grade zirconia conforming to ISO 13356 standard reach specific activity levels similar to the one of human body (about 40 Bq/kg), due to the natural abundance of ^{90}K in blood, muscles and marrow. (*Capannesi et al., 1992; Porstendörfer et al., 1996; Piconi et al., 2014; Bavbek et al., 2014*).

Carcinogenesis is not observed after intra-peritoneal injection in mice, or after implant of disk and tubes in rabbit muscles. Also the absence of aberration of the chromosomal patterns in cells co-cultured on zirconia plates has been reported (*Piconi and Maccauro, 1999*). Carcinogenicity tests (Ames test) and teratogenicity tests (cellular chromosome aberrations) in the presence of $ZrO_2 + Y_2O_3$ doped with 0.5 ppm UO_2 have been performed in vitro, both with negative results. (*Covacci et al., 1999*).

Alumina-Zirconia Composites

The abandon of zirconia in 2001 opened a technological gap in orthopedics. At the turn of the century, it was clear that there was the need of for additional sizes, increased reliability and longevity of ceramic components in arthroplasty. This pushed the industry to develop higher strength composite ceramic materials. Researcher then turned their attention towards different zirconia-toughened ceramics, and significant results were obtained in the development of composites having alumina as main component identified as Zirconia-Toughened Alumina (ZTA) either having zirconia as main constituent, then called Alumina-Toughened Zirconia (ATZ).

The first one introduced into the market about 2002 was the alumina matrix composite (AMC) BIOLOX®delta, made by CeramTec GmbH, (Plochingen, Germany) (*Burger and Richter, 2001*).

The basic concept throughout its development was to preserve the excellent properties of alumina as an implantable ceramic material and to increase its mechanical properties, specifically its fracture toughness. The resulted in a material formed by a fine grained high purity alumina matrix (approximately 80 vol%) combined with three different oxides in order to achieve the desired enhanced properties. The balance of the material mass is constituted by evenly dispersed YTZP zirconia particles with an average grain size of roughly 0.27 μm (17 vol%) and by a complex zirconium aluminate phase with a maximum length of approximately 5 μm and an aspect ratio of 5–10.

Two mechanism are concurring to toughen and to reinforce this composite: the phase transformation of YTZP triggered by the tensile stresses in proximity of a crack tip is an effective energy dissipative mechanism. Moreover, the volume expansion associated to the transformation has to win the high stiffness of the alumina matrix and then has to overcome an higher energy threshold. The resulting compressive stresses field is high efficient in blocking further advance of the crack in the microstructure. The elongated zirconium aluminate crystals nucleated into the composite microstructure during sintering acting as short fibers give a further contribution both to reinforce both to toughen further the material. Chromium oxide is added giving the material its characteristic pink color.

A different approach was followed by researchers working in Mathys Orthopedic (Ermsdorf, Germany, now) who developed a material mostly constituted by zirconia (Ceramics®). In this composite zirconia is present as transformable YTZP both as untransformable cubic zirconia, that with the minor constituent alumina is forming the matrix of the composite (*Begand et al., 2005; Schneider et al., 2008*).

Alumina-Toughened Zirconia (ATZ) composite for orthopedic joint replacement was presented on 2005 by Begand *et al.* (2005) and was introduced in the orthopedic market on 2007 by Mathys Orthopédie (Bettlach, Switzerland) under the tradename Ceramys®. As reported by Schneider *et al.* (2008) large part of this material (about 60 vol%) is tetragonal zirconia, the balance being cubic and some monoclinic.

The mechanical behavior of the material reported by these Authors are remarkable. Nevertheless, due to the permanence of concerns on zirconia, the diffusion of ATZ in arthroplasty seems limited. Kyocera (Kyoto, Japan) followed an original approach developing a ZTA (BioCeram® AZ209) in which zirconia was stabilized in the tetragonal state by residual stresses only (Clarke *et al.*, 2016). More recently, this company presented a further ZTA reinforced by platelet-like alumina crystals (BioCeram® AZUL™) owing its tradename to its characteristic blue color due to the presence of Cobalt among its additives (Ikeda *et al.*, 2017).

Orthopedic Applications

The large part of oxide ceramic in orthopedic applications are ball heads and inserts for THR bearings. Today, ceramic bearings are introduced in shoulder joint replacements, while ceramic knee replacement are already in clinical use, although still in a limited number. Kyocera Medical (Kyoto, Japan) – which is a pioneer in this field – is making femoral condyles in zirconia (Y-TZP) that are implanted in Japan since 2001. In Europe, only CeramTec (Plochingen, Germany) is manufacturing alumina-zirconia composite components for the knee implants produced by Lima Corporate (Villanova di San Daniele, Italy) and by Peter Brehm (Weisendorf, Germany).

It is well known that the use of ceramic bearings minimizes at the best possible with present technology the wear debris released from the joint. In addition, the cytotoxicity of the ceramic debris is the minimum among the different materials (polymers, metals) used in joint replacement bearings (Fisher *et al.*, 2006). A low wear is especially relevant in joint replacements, because of the osteolysis due to the body reactions to wear debris and the consequent aseptic loosening of the implants is still among the main reasons of revision surgeries. Because of the low wear, joint replacements with ceramic bearings are especially suitable for more active patients, as well as for the younger ones with longer life expectations (Black, 1997).

So far, alumina represents a minor share (15%–20%) of the market of ball heads and inserts for Total Hip Replacements (THR) while the use of zirconia (Y-TZP) in THR ball heads has been practically abandoned since 2001 (Piconi *et al.*, 2007). Also in the knee alumina has left place to YTZP or zirconia-alumina composites, that are “the ceramic” in orthopedic today. The main manufacturer worldwide (CeramTec GmbH, Plochingen, Germany) claims to have sold by mid-2019 more than ten million ball heads and inserts for THR made out BIOLOX®delta Alumina Matrix Composite (AMC) and more than five millions made out the former BIOLOX® alumina. Thanks to the improved mechanical properties of BIOLOX®delta in comparison to the ceramics formerly used, as illustrated in Table 1 in the following, it was possible to develop ceramic components for joint replacements with design more challenging than in the past.

The different composite ceramics now on the market are not only providing a reduction in wear of the bearing, but also higher reliability. Massin *et al.* (2014) reported the data of the French National Agency for Medicines and Health Products Safety (ANSM) on the fracture frequencies of BIOLOX®delta inserts (0.025%) and of ball heads (0.0013%), that are closely matching the 0.001% (1/100.000) for heads and 0.021% for inserts reported as resulting by the manufacturer's records. that (Sentuerk *et al.*, 2016).

Oxide Ceramic in Total Hip Replacements

Notwithstanding the high number of Total Hip Replacements presently offered by the implants manufacturers on the orthopedic market worldwide, their design is based on several common features, depicted in Fig. 1. The femoral component is constituted by a stem to be inserted in the femoral canal hosting at its proximal extremity a ball head, the head (ceramic or metal) is articulating into the acetabular component of the implant (the cup, the socket) constituted by an insert (ceramic or polymeric) fixed into a metallic shell. Both the stem both the cup may be cemented into bone, either positioned cementless.

As remarked in the Introduction, the taper connection developed for the head-stem in THR by the German researchers in the early 1970 made possible the modularity now widely used in a number of joint replacements. The taper connection allows modular design, e.g., a stem may host metallic or ceramic heads, while a modular acetabular socket that can host ceramic or polyethylene inserts. The number of available sizes give rise to a family of bearings, providing the selection of the wear couple that suits better the needs and the anatomy of the patients.

Ceramic heads are classified by external diameter, neck length and taper type and size. The standard series of ball head diameters is 28, 32, 36, 40, 44 mm. For any diameter the depth internal of the conical bore can be selected in four steps, identified by the resulting neck length of the implant, i.e., + 5 (XL, Extra Long neck), + 3.5 mm (L, Long neck), 0 mm (M, Medium neck) and – 3.5 mm (S, Short neck). Whatever the ball type, the taper connection transfers the loads due to patient activity to the ceramic head generating two main tensile stresses in the ceramic head, e.g., in the head dome, and homoradial (hoop) stresses close to the taper surface. (Andrisano *et al.*, 1990; Middleton *et al.*, 1994; Weisse *et al.*, 2003).

The taper fitting more common in Europe is the so-called 12/14. It is noted that this denomination is not corresponding to the real geometry of the taper, whose angle, length, upper and lower base diameter may differ largely among the different implant systems. In addition, implants of different models made by the same manufacturer may have different design of the taper

Fig. 1 Schematic of a THR with ceramic-on-ceramic bearing joint. Reprinted from Piconi, C., 2017. Ceramics for joint replacement: Design and application of commercial bearings. In: Palmero, P., Cambier, F., De Barra, E. (Eds.), *Advances in Ceramic Biomaterials*. Duxford: Woodhead, pp. 129–179.

connection. Calés and Stefani (1998) analyzed 20 different taper design, observing significant variations between the top of the trunnion with respect to the center of the ball head and of the distance between the top of the trunnion and the bore rim, both parameters resulting relevant for the stress distribution within the ball head. In addition, the variability among the tapers of the different implant systems are enhanced by the machining tolerances and by the surface finish of the taper itself, that are specific to each manufacturer and to each THR system (Munir *et al.*, 2015). In consequence of the many variables that characterize each taper, it is evident that coupling between stem and head shall not be made at random, but carefully following the instructions given by the implant manufacturer.

In the large majority of hip replacement systems now on the market also the acetabular components (the socket, the cup) have modular design, consisting in a metallic shell (the metal back) hosting a ceramic or UHMWPE insert (or inlay) fitted into the shell by a taper connection. Whatever the design of the implant system, the mechanical interlock between the liner and the metal back has to assure the stability of the insert, that once seated into the metal back has to resist to pull out, to torsion moments, to lever out moment due to the forces exerted on it during its clinical use.

To the extent of this chapter, heads are ceramic, but the use of metallic heads (usually CoCr-Alloy) is widespread and also all-polyethylene cups are in clinical use. Consequently, THR bearings are categorized as Hard-on-Hard or Hard-on-Soft bearings.

The choice of the bearing couple marks the difference among Countries: while in the EU, Japan, Korea there is a prevalence of the use of ceramic heads while in the USA and Australia the CoCr-alloy is the material of choice for THR heads. In the acetabular side cross-linked UHMWPE [XLPE] are the material more used worldwide, but in France and in Korea ceramic-on-ceramic is the preferred bearing, as depicted in Fig. 2. It is note that the market is evolving very fast, and the use of ceramic heads in arthroplasty is growing, especially in couple with XLPEs.

The hard-on-soft configuration is traditional in THR since 1960, when Sir John Charley selected Ultra High Molecular Weight Polyethylene (UHMWPE) for the acetabular component of Low Friction Arthroplasty, after the first attempts made with polytetrafluoroethylene (PTFE) resulted in a series of failures. The UHMWPE debris generated by the wear of the bearing were identified as the origin of the cascade of events leading to aseptic loosening of the implants since a long (Willert and Semlitsch, 1977). The increase in number of hip arthroplasties performed in more active patients has enhanced the relevance of the risk of complications related to wear debris. As put in evidence in the introductory part of this section, several ceramics can be used for the ball heads and a number of polymeric materials that can be used for the articular surface of the cup.

Current hard-on-soft solution is to couple ceramic ball heads are coupled to cross-linked polyethylene.

Fig. 2 Use of ceramic components in total hip replacements in selected countries (CoC: ceramic-on-ceramic bearing. CoP: ceramic-on-polyethylene bearing). Reprinted from Piconi, C., 2017. Ceramics for joint replacement: Design and application of commercial bearings. In: Palmero, P., Cambier, F., De Barra, E. (Eds.), *Advances in Ceramic Biomaterials*. Duxford: Woodhead, pp. 129–179.

A number of investigations were carried out to improve the tribological behavior of UHMWPE, e.g., by the introduction of second phases (e.g., glass fibers, carbon fibers). Today, the solution that is widespread in arthroplasty consists in improving the mechanical properties of UHMWPE by the increase of the cross-linking of the molecular chains. Several cross-linked polyethylenes were developed with different process and clinical results, as comprehensively illustrated by Brach del Prever *et al.* (2009) and by Oral and Muratoglu (2016).

Artificial joints are to be designed to enable the whole range of physiological movements (flexion, extension, abduction, adduction and rotation) then THR are currently designed to allow a Range of Motion (ROM) of at least 120°. The increase in diameter may allow ROM of 135–140°, and then 36 or 40 mm bearings are now usual in many THR systems. The higher ROM decrease the risk of impingement of the cup rim on the stem neck (Willmann *et al.*, 2000) while increase the “jumping distance” of the joint, e.g., the displacement necessary to dislocate permanently the head from the socket. This is especially relevant for young and active patients, or for patients demanding high joint mobility due to their resting position (squatting).

The main drawback of the increased bearing diameter is the increase of the overall diameter of the socket. This is negative for the patient’s bone stock, both for the suitability of the implant for smaller anatomies (e.g., female or Asian patients). In consequence, to limit the thickness of the cup is necessary to limit by limiting the thickness of the shell and of the insert, without compromising the stiffness of the whole cup, is a challenging task in the design of the implant (Dold *et al.*, 2016).

In the light of the above, the use of ceramic in larger bearings is very interesting, because of low friction of ceramic-on-ceramic surface that do not lead to increase in wear or torque for bigger head diameter.

ZTA composites (BIOLOX®delta) are making feasible the design of cementless all-ceramic cups. In addition, it has been demonstrated in animal models the effectiveness of treatment giving bone bonding behavior to the external surface of ceramic cups, thus achieving osseointegration of the device (Schreiner *et al.*, 2002, 2012; Theelke *et al.*, 2009).

Oxide Ceramic Hip Resurfacing

The resurfacing of the femoral head is an interesting alternative to THR for high activity patients, because it is bone-sparing and reducing dislocation risk. Nevertheless, its survivorship in female patients is lower than in males because of the reduced head size, especially is lower than 50 mm.

The alternative is to make hip resurfacing devices by ceramics.

During the 1970s Locke and Stärk (Rosenthal Technik Lauf, Germany) developed several very innovative alumina devices. Remarkable is the femoral head resurfacing alumina femoral cup to be coupled with an alumina uncemented cup. (Salzer *et al.*, 1978). The outcomes of these devices was unsatisfactory. Today, thanks to improved design and materials the prototypes of ceramic resurfacing devices are under development, as reported recently in several works (Dickinson *et al.*, 2011; Pandorf and Preuss, 2019; Vogel *et al.*, 2019). A ceramic resurfacing device made out the alumina matrix composite BIOLOX®delta (CeramTec, Plochingen, Germany) is depicted in Fig. 3.

Oxide Ceramic Knee Joint Replacements

The issue of wear is becoming more and more relevant in knee replacements because the number of implants performed each year is growing, and more and more young patients are today candidates for the implant of a knee replacement. The use of a ceramic in knee replacement has several potential advantages; first, an improved lubrication of the articulating surface due to the high

Fig. 3 Ceramic hip resurfacing. Courtesy: Medical products Division, CeramTec GmbH, Plochingen, Germany.

wettability of ceramic surface by the synovia liquid and then a lower wear rate of the PE liner on the tibial component. A further reason for the selection of ceramics in knee replacements is linked to the growing incidence of allergic reactions to metal ions, and of the wide metallic surface that patients may develop for the presence of different metallic implants in several anatomical districts of the body. The Australian Orthopedic Register shows that about 2% of TKR revision surgeries is due to “metal related pathologies” (Australian Orthopedic Association, 2016). The subject is still debated (Münch *et al.*, 2015; Middleton and Toms, 2016; Innocenti *et al.*, 2017; Saccomanno *et al.*, 2019). However, it has been noted that 15 in 23 different TKR systems used clinically in the UK had a “anallergic” version obtained by ceramization of the metallic components, both version having identical design and size (Ajwani and Charalambous, 2016).

A reduction in PE wear can also be expected for the better scratching resistance of the ceramic surfaces, in comparison to metallic alloys, that will save the status of the polished articulating surfaces. (Solarino *et al.*, 2017) Moreover, the use of ceramic devices is reducing the artifacts in CT – scans of the joint after surgery (Kasperek *et al.*, 2019).

The development of ceramic knee replacements

Although the first use of alumina in the knee is due to the prof. Langer who used unicompartimental tibial plateau replacements in Jena, (Langer and Blumentritt, 1987; Langer, 2002) the development of ceramic Total Knee Replacement (TKR) was started in Japan on 1970s by the late prof. Hironobu Oonishi, a pioneer in the development of ceramic devices. These TKRs (the so-called KOM-1) – made by the company Kyocera (Kyoto, Japan) – were formed by an alumina femoral component articulating on a polyethylene insert hosted on an alumina tibial plateau, and were implanted cementless in 134 patients. (Oonishi, 1990, 2006) Kyocera developed also unicompartimental knee replacements that showed high success rate at controls made at an average 42 months after surgery (24–68 months) (Atsui *et al.*, 1997).

Since then several other TKR design based on alumina were developed in Japan, such as the Low Friction Anatomical (LFA-1), the Yokohama Medical Ceramic Knee (YMCK), the Bisurface knee replacement designed by the University of Kyoto all made by the company Kyocera (Kyoto, Japan), and the Kyoto Ceramics-1 (KC-1) (Solarino *et al.*, 2017).

Other researchers focused their work on the development of TKRs with zirconia femoral components. Payten and Ben Nissan (Payten and Ben Nissan, 2000), reported the design of a modular knee replacement in its femoral component Mg-PSZ inserts clipped on the metallic baseplate. Experimental THR with YTZP femoral condyles gave unsatisfactory short-outcomes in 20 patients in the University Hospital Motol (Praha, Czech Republic), and the development of these devices looks abandoned by now (Vavřík *et al.*, 2008; Veigl *et al.*, 2011).

Preliminary results of clinical trials carried out in the USA on TKRs with Y-TZP condyles are reported in the literature, but these studies looks have been uneventful so far (Blaise *et al.*, 2002; Bal *et al.*, 2005). The contemporary development of femoral components for knee arthroplasty made out the AMC BIOLOX®delta (CeramTec, Plochingen, Germany) may have contributed to the dismissal of these projects (Heimke *et al.*, 2002).

So far, BIOLOX®delta components are used in two different knee replacements, the Multigen Plus Total Knee Replacement designed by LIMA Corporate (San Daniele del Friuli, Italy) (Dalla Pria *et al.*, 2006) and the BPK-S designed by Peter Brehm (Weisendorf, Germany).

Fig. 4 The multigen total knee replacement with ceramic femoral component (Courtesy CeramTec GmbH, Medical Products Division, Plochingen, Germany). Reprinted from Piconi, C., 2017. Ceramics for joint replacement: Design and application of commercial bearings. In: Palmero, P., Cambier, F., De Barra, E. (Eds.), *Advances in Ceramic Biomaterials*. Duxford: Woodhead, pp. 129–179.

Fig. 5 The BPH-S total knee replacement with ceramic femoral component and tibial tray (Courtesy CeramTec GmbH, Medical Products Division, Plochingen, Germany). Reprinted from Piconi, C., 2017. Ceramics for joint replacement: Design and application of commercial bearings. In: Palmero, P., Cambier, F., De Barra, E. (Eds.), *Advances in Ceramic Biomaterials*. Duxford: Woodhead, pp. 129–179.

The more striking difference between the two devices is in the tibial component. In the Multigen Plus – depicted in [Fig. 4](#) - it consists in a monoblock XLPE component, while in the BPK-S – depicted in [Fig. 5](#) - a BIOLOX®delta tibial tray hosts a semi-constrained XLPE insert, with a stump in its inferior part articulating with the tray to control its motion. The clinical and

radiological outcomes and survival rate of both devices are comparable to other metallic TKA systems (Bergschmidt *et al.*, 2015; Meier *et al.*, 2016).

Oxide Ceramics in Shoulder Joint Replacement

Besides hip and knee replacements here is today a new interest for using ceramic components in shoulder replacement, as the glenoid component of the implant. The replacement of the shoulder joint with ceramic devices has been attempted in the past. The device described in the US Patent issued by Zeibig and Locke is an alumina “three-part implant...for an upper arm bone” (Zeibig and Locke, 1976). Sim *et al.* reported the implant of a ceramic humeral component (Rosenthal, Lauf, Germany) after resection due to bone tumor (Sim *et al.*, 1980). Later, Huckstep and Sherry reported the use in three cases the implant of shoulder replacement with alumina head for limb salvage due to bone tumor (Huckstep and Sherry, 1996).

The development achieved in the last years in shoulder replacements stimulated the interest for using ceramic components in Total Shoulder Replacement (TSR) systems. The component of reference is the glenoid head. Several models are on the market, the one manufactured by CeramTec is illustrated in Fig. 6. Enomoto (2001) reported the short term results of 11 cementless artificial humeral head replacement performed between 1993 and 2000 using alumina-ceramics head Physio-shoulder system (Kyocera, Japan), while a glenoid ball head coupled to a ceramic humeral insert is used in the Unic® TSR (Evolutis®, Brennon, France). Ceramic glenoids or ceramic humeral heads are also used in the TSRs of the Affinys® system (Mathys Orthopedie, Bettlach, Switzerland) (Bell and Coghlan, 2014).

Oxide Ceramics in Ankle Joint Replacements

First attempts for using alumina in an ankle joint replacement were made in Japan since the early 1980s. The TNK total ankle replacement – that has tibial and the talar components made out high density alumina – was introduced in the Japanese market by Kyocera (Kyoto, Japan) in the early 1990 and it is still in clinical use. In TNK, the tibial component hosts a UHMWPE insert on the articular surface. The bone-contacting surfaces of the tibial and talar components are coated with alumina beads, forming a porous surface aimed to achieve the cementless fixation of the implant by bone ingrowth. The review of clinical experience with two successive generations of TNK devices demonstrated that improved results could be achieved using cement to stabilize the implants in situ (Nishikawa *et al.*, 2004; Takakura *et al.*, 2004). More recently, osteonecrosis of the talus has been treated with alumina patient-specific talar replacements (Taniguchi *et al.*, 2015).

Fig. 6 Ceramic glenoid head (Courtesy Medical Products Division, Ceramtec GmbH, Plochingen, Germany). Reprinted from Piconi, C., 2017. Ceramics for joint replacement: Design and application of commercial bearings. In: Palmero, P., Cambier, F., De Barra, E. (Eds.), *Advances in Ceramic Biomaterials*. Duxford: Woodhead, pp. 129–179.

Oxide Ceramics in Finger Joint Replacements

Several prosthetic implants have been designed to treat the proximal interphalangeal and metacarpophalangeal joints affected by post traumatic conditions or rheumatoid arthritis.

The literature mentions a ceramic device only, the Orthosphere® (Wright Medical, Austin TX). This device, consisting is a zirconia sphere, was used in the interpositional arthroplasty of the thumb carpometacarpal joint, as reported by Calandruccio and Jobe (Calandruccio and Jobe, 1997).

Oxide Ceramics in Disk Replacement

Ceramics devices are used in spine arthrodesis (the synthesis of two or more adjacent vertebral bodies) and in spine arthroplasty by Total Disk Replacements (TDR). The main advantage of TDR over arthrodesis consists in the preservation of the relative motion of the vertebral bodies. So far.

A further TDR with ceramic components is the the Discocerv™ (Scient'x, Voisin Le Bretonneaux, France) intended to replace disks in the cervical spine (C2–C7). It is formed by two titanium alloy (Ti-6Al-4V) endplates which external profile fits into the native disk space. In their interior there is the bearing, formed by a convex alumina disk articulating on a concave Y-TZP disk. (Ramadan *et al.*, 2007; Enan *et al.*, 2011).

A further TDR using PEEK-ceramic bearing with design based on the KineFlex® 11C Cervical TDR (SpinalMotion, Mountain View, CA, USA) has been tested. This device is formed by two PEEK endplates hosting between them a mobile zirconia-toughened alumina ceramic core (CeraSurf1-p; CoorsTek1 Medical, Grand Junction, CO, USA) (Siskey *et al.*, 2016).

Silicon Nitride

Introduction

Silicon nitride is the name given to a family of structural ceramics that is used for high temperature and wear resistant applications which include turbocharger rotors, glow plugs, bearings, cutting tools, valves and certain refractory components (Riley, 2000; Petzow and Herrmann, 2002; Hampshire, 2016). Silicon nitride, general stoichiometric formula Si_3N_4 , may be formed as a dense ceramic at temperatures in the range 1750–1900°C by hot pressing (HPSN), pressureless sintering (SSN), hot isostatic pressing (HIPing) or gas pressure sintering (GPS) which results in a ceramic with high flexural strengths (600–1200 MPa), high fracture resistance, high thermal shock resistance, high creep resistance, high hardness, and excellent resistance to erosion.

Silicon nitride may also be formed as a microporous ceramic by reaction bonding which involves nitridation of silicon powder compacts at 1200–1400°C during which silicon nitride crystals grow within the pre-existing pores of the silicon powder compact (Moulson, 1979). The original dimensions of the component remain virtually unchanged during nitriding (linear shrinkage <0.1%), allowing complex shapes to be machined to their final size either before nitriding in the ceramic green state or after partial nitriding at 1000–1200°C to make the material stronger. The final product is known as RBSN (Reaction Bonded Silicon Nitride) (Ziegler *et al.*, 1987) and contains up to 25% microporosity which limits its mechanical strength (200–250 MPa) for certain engineering applications. By addition of oxide additives to silicon powder compacts prior to nitriding, a dense form of silicon nitride may be subsequently produced by sintering the RBSN at ~1750°C, the resulting ceramic known as Sintered Reaction Bonded Silicon Nitride (SRBSN) (Mangels and Tennenhouse, 1980). However, the presence of porosity may be beneficial for biomedical applications. The amount of porosity within a ceramic implant is an important design parameter. Low porosity implants with reasonable fracture toughness are essential for load bearing applications whereas high porosity or graded porosity devices would be advantageous for bone fixation (McEntire *et al.*, 2015).

Sintering of pure silicon nitride is quite difficult because self-diffusivity is low and species only become sufficiently mobile for sintering at temperatures where the decomposition of silicon nitride commences (>1850°C). Thus, alternative approaches were developed by the use of densification additives to create the conditions for liquid phase sintering. Oxide additives ($\text{Al}_2\text{O}_3 + \text{Y}_2\text{O}_3$ or $\text{RE}_2\text{O}_3 - \text{RE} = \text{Rare Earth}$) are mixed with α -silicon nitride powder before forming of the green ceramic into a component shape. Firing is carried out at sintering temperatures of 1750–1900°C where reaction of the additives with silica present on the Si_3N_4 particle surfaces and some of the nitride itself occurs to form an oxynitride liquid which promotes densification by solution-precipitation (Riley, 2000; Hampshire, 2016). The α - Si_3N_4 dissolves in the liquid and is precipitated as the β -form of Si_3N_4 which grows as prismatic hexagonal rod-like crystals that eventually impinge on each other forming an interlocking microstructure of high aspect ratio β -grains and intergranular glass films (Sun *et al.*, 1998; Hampshire and Pomeroy, 2012). By varying the type and amounts of the mixed additives, the chemistry of the grain boundary phase is modified and this has a significant effect on the grain size and aspect ratios of the β - Si_3N_4 grains, resulting in a range of materials with tailored strength and fracture toughness (typically $\geq 6 \text{ MPa m}^{1/2}$). An advancing crack has to take a more complex high energy route through the ceramic and continued crack propagation is restricted by grain bridging and pull-out in the crack wake. This reduces tensile stresses at the crack-tip resulting in increasing resistance to crack propagation as the crack extends, a phenomenon referred to as R-curve behavior (Fünfschilling *et al.*, 2009).

SiAlONs

Other members of the silicon nitride family are the SiAlONs which are solid solutions of Si, Al, O, and N, based on the silicon nitride structure. β' -SiAlON is formed when oxygen replaces nitrogen in the β - Si_6N_8 structure while, at the same time, silicon is replaced by aluminum to maintain charge neutrality (Jack and Wilson, 1972). The solid solution composition is

with z values in the range 0–4.2 and the structure retains the 6:8 metal: non-metal ratio of β - Si_6N_8 . β' -sialons still require the use of sintering additives such as Y_2O_3 and other RE_2O_3 in order to densify the ceramic (Ekström and Nygren, 1992). Microstructures are similar to β - Si_3N_4 with elongated hexagonal grains of β' -sialon but a reduced amount of intergranular glass phase.

Similarly, α' -SiAlONs (α') are based on the α - $\text{Si}_{12}\text{N}_{16}$ unit cell with general composition (Hampshire *et al.*, 1978):

In α' -SiAlON, partial replacement of Si^{4+} by Al^{3+} occurs if, at the same time, charge compensation is effected by the accommodation of other ions, $\text{M} = \text{Li}^+, \text{Ca}^{2+}, \text{Y}^{3+}$, or other rare earth lanthanide ions (Ln^{3+}), in the two interstitial sites (x) in the unit cell. x (<2) is determined by the valence (v) of the M^{v+} ion. As with β' , oxide additives are used as densification aids but they also provide M^{v+} ions for stabilization of α' (Mandal, 1999).

The two SiAlON phases, α' and β' , can coexist depending on the sintering additives used. Therefore, there are more variables to be used as design parameters for SiAlON ceramics and the amount of α' -SiAlON can be varied from 0% to 100% continuously and the type and amount of intergranular phase can also be modified by using mixed additives. These are usually combinations of CaO and two rare earth lanthanide oxides which allow more easier densification but on subsequent heat treatment, the final properties of the SiAlON ceramics can be tailored so that when high hardness is needed, α' -SiAlON content is increased and when higher toughness is required, then additive chemistry is changed to give predominantly β' -SiAlON (Calis Acikbas *et al.*, 2012). These ceramics are already available as cutting tools or refractories and are being developed as wear parts.

Silicon Nitride as a Biomedical Material

During the late 1980s, the effect of an in vitro and in vivo investigation of silicon nitride (RBSN) on rabbit skeletal cells and tissue was carried out (Howlett *et al.*, 1989). Segmental femoral Si_3N_4 endoprostheses were implanted in each of three adult rabbits and the osseous reactions monitored during their natural life. Each implant was enclosed by a stable cuff of bone within four months of implantation and remained unchanged during the rest of the animal's life. Autopsies confirmed the radiographic observations and tissue adjacent to each prosthesis was morphologically normal.

At around the same time, some of the same authors (Sorrell *et al.*, 2004) were involved in a human clinical trial in Australia to determine the capability of silicon nitride as an arthrodesis device in the lumbar spine. 30 patients with long-term spinal degeneration problems underwent anterior interbody fusion of the lower spine using reaction bonded silicon nitride intervertebral spacers. A control population of 10 underwent the same procedure using autologous bone. After 5 years, there were no significant differences in patient satisfaction or rates of union between the autologous bone grafts and the RBSN implants, but there was a significant reduction in interspace collapse with the silicon nitride implants. After 10 years, progressive degeneration was observed in 13 of 16 cases assessed which were thought likely to be the result of stress shielding due to elastic modulus mismatch.

Evidence from another study (Kue *et al.*, 1999) showed that reaction bonded silicon nitride has a non-toxic, biocompatible ceramic surface for the propagation of functional human bone cells in vitro.

Given the excellent combination of mechanical and tribological properties of dense silicon nitride, investigations of other properties critical in biomedical environments were examined such as cytotoxicity, wetting behavior, chemical stability in aqueous media, including simulated body fluid (SBF) and wear rates in physiological solutions with a view to developing silicon nitride components for orthopedic applications (Bal and Rahaman, 2012). Not only is silicon nitride non-toxic, but the material encourages cell adhesion, normal proliferation and differentiation. Cell growth, viability and morphology on silicon nitride were comparable with Ti, and polished Si_3N_4 surfaces appeared to promote cell growth.

Prosthetic hip and knee replacement bearings require biomaterials with low wear rates and favorable frictional coefficients that remain stable in vivo for their service life. Silicon nitride wear couples showed low sliding wear rates both in phosphate-buffered saline (PBS) and in bovine serum compared with the other tested wear couples (Olofsson *et al.*, 2012). Tribofilms were built up on silicon nitride surfaces in both environments, controlling the friction and wear characteristics. Under these test conditions, the contact surfaces of silicon nitride become ultra-smooth as a result of tribochemical polishing and the friction becomes very low at increasing sliding distances.

In view of the possibility of using silicon nitride as a ceramic for structural orthopaedic implants, another study (Mazzocchi and Bellosi, 2008; Mazzocchi *et al.*, 2008) investigated three different silicon nitride based materials: (1) 90.0 vol% Si_3N_4 + 10.0 vol% bioglass, (2) 91.3 vol% Si_3N_4 + 8.7 vol% MgO, and (3) a $\text{Si}_3\text{N}_4/\text{TiN}$ composite with 65.0 vol% matrix (93 wt% Si_3N_4 + 2 wt% Al_2O_3 + 5 wt% Y_2O_3) + 35.0 vol% TiN. Some critical features for biomedical applications were investigated: (i) the wetting behavior against aqueous media, including physiological solutions; (ii) the chemical stability in water and in physiological solutions; and (iii) the wear resistance, measured under experimental procedures that simulate the conditions typical of the hip joint prosthesis. For the $\text{Si}_3\text{N}_4/\text{TiN}$ composite material, some oxidation of TiN affected the friction coefficient but for the monolithic silicon nitrides, friction coefficients were found to be lower than results reported in the literature and the wear resistance is an order of magnitude higher than those reported for other ceramics used for hip joints. The results indicated that silicon nitride was a suitable biomaterial for bone substitution in load bearing prostheses.

Porous silicon nitride-based ceramics, with pore structures similar to that of trabecular bone consisting of an interconnected macroporous network, were prepared by a replica method with polyurethane sponge as pore forming agent (Bodišová *et al.*, 2013). Two porous ceramics were prepared: (1) air-sintered silicon nitride (following burn-out of the polyurethane) and (2) sintered reaction-bonded silicon nitride. No oxide sintering additives were used. Using the same characterization methods as for human bone samples, the pore size distributions in the most important dimensional regions, i.e., under 50 nm and over 100 μm were measured and found to be similar to that of the bone, especially in the air-sintered silicon nitride ceramics. Likewise, the mechanical properties of the air-sintered silicon nitride were very close to those of bone. In the case of sintered reaction-bonded silicon nitride further optimization is required in terms of enhancing the meso- and nano-pore contents and decreasing the hardness and elastic modulus values. The non-cytotoxicity of both forms of porous silicon nitride was confirmed by MTT proliferation test.

Bacteriostasis studies have been conducted on silicon nitride which was compared with titanium (Ti) and polyether ether ketone (PEEK) using five separate nosocomial bacterial strains in vitro (Gorth *et al.*, 2012). Lower amounts of biofilm formation (up to 90%) and fewer live bacteria were consistently found on Si_3N_4 than either of the other two biomaterials. As might be expected, PEEK generated the highest amount of biofilm and harbored the most live bacteria. They postulated that reasons for the observed differences

Fig. 1 Silicon nitride bioceramic components for joint and spinal reconstruction. Courtesy of SINTX Technologies, Salt Lake City, Utah, USA.

were likely due to: (i) improved hydrophilicity of the ceramic in comparison to the moderately and highly hydrophobic metal and polymer, respectively; (ii) chemical moieties on the surface of Si_3N_4 including charged amino and silanol species of SiNH_3^+ , SiOH_2^+ , SiO^- , SiNH_2 , and SiOH , all of which may act to repel microbial attachment; and (iii) a micro-textured surface for Si_3N_4 , which may also prevent biofilm formation. These features were not observed with the other two biomaterials.

The rigid and permanent fixation of an alloplastic medical device with native bone is referred to as osseointegration and is just as important as wear resistance. Samples of silicon nitride implanted in tibias of rabbits were evaluated eight weeks after implantation (Guedes e Silva *et al.*, 2008). The Si_3N_4 and the adjacent bone tissue were analyzed by scanning electron microscopy in order to verify the bone growth around the implants and its morphology and the interaction between the implant and the bone. Bone growth had occurred mainly in the cortical areas. In another study of a highly porous ($\sim 72\%$) silicon nitride (Anderson and Olsen, 2010), osseous penetration of up to 3 mm was observed with excellent vascularization twelve weeks after implantation in an ovine model.

The extents of osseointegration of silicon nitride, PEEK, and titanium were compared in Wistar rats (Webster *et al.*, 2012). Silicon nitride had improved osseointegration over the other two biomaterials at all times up to 3 months post-operatively. New bone formation in the surgical area around the implants was 69% for Si_3N_4 and only 24% for PEEK and 36% for Ti. When implants were pre-inoculated with 104 *Staphylococcus epidermidis*, new bone formation (after 3 months) was 41% for Si_3N_4 and only 21% for PEEK and 26% for Ti. Live bacteria were identified around PEEK (88%) and Ti (21%) implants, whereas none were present on the silicon nitride.

Silicon Nitride Biomedical Devices

Silicon nitride components for biomedical applications, as shown in Fig. 1, are now being manufactured by SINTX Technologies, formerly Amedica Corporation (Salt Lake City, UT, USA). FDA certification has been approved for various products, including ceramic interbody vertebrae fusion devices for cervical and thoracic spine surgery. The company is also developing silicon nitride for new biomedical devices for the spine, dental, oral maxillofacial, podiatry, and arthroplasty markets. The silicon nitride is densified using ~ 6 wt% Y_2O_3 and ~ 4 wt% Al_2O_3 as additives and is sintered in nitrogen at $> 1700^\circ\text{C}$ for ~ 3 h, followed by hot-isostatic pressing $> 1650^\circ\text{C}$ under a nitrogen pressure of > 200 MPa for ~ 2 h.

Fully dense silicon nitride, under development as bearings for hip and knee joint replacements, was found (Bal *et al.*, 2009; Rahaman and Xiao, 2018) to be chemically stable when subjected to accelerated aging for 100 h at 120°C and 0.1 MPa steam in a surgical autoclave. X-ray analysis showed no measurable difference in phase composition following treatment and flexural strength remained within 1 standard deviation (± 36 MPa) of the mean strength (936 MPa). In addition, Si_3N_4 exhibits excellent radiographic visibility as a partially-radiolucent material (Rahaman and Xiao, 2018).

The surface texture and chemistry of these silicon nitride materials has been tailored by applying thermal, chemical, and mechanical treatments, to yield ultra-smooth or highly fibrous surface structures that lead to enhanced osseointegration and bacterial resistance without compromising bulk mechanical properties (Bock *et al.*, 2015). Smooth surfaces are required for bearings in hip and knee arthroplasty because conforming surfaces result in higher contact area between components and hence lower stresses and wear rates. In contrast, surface roughness can markedly influence the response of cells *in vitro* and *in vivo* for implants intended for osseointegration and bacteriostasis. The treatments included grinding and polishing, etching in aqueous hydrofluoric acid, and heating in nitrogen or air. The treated surfaces were characterized using a variety of techniques to assess morphology, surface chemistry and phase composition, surface charging and wetting behavior.

The surface of as-fabricated Si_3N_4 exhibited anisotropic and stochastically oriented β - Si_3N_4 grains covered with a thin $\text{Si}_2\text{N}_2\text{O}$ -like passivation layer, strong negative charging at biologic pH, and moderate hydrophilicity that improved over time as capillary forces drew water into the spaces between the surface grains. Etching in HF produced a surface composition with a higher N/Si and a lower

O/Si ratio than as-fabricated materials – which exhibited strong negative surface charging at homeostatic pH and moderate hydrophilicity.

Thermal treatment in N_2 produced a surface coated in crystalline β -SiALON precipitates whose concentration decreased as a function of depth up to 90 μm . Thermal treatment in an oxidizing atmosphere resulted in a surface composition effectively the same as amorphous SiO_2 . It also exhibited extremely low wetting angles and charging behavior that mimicked pure silica. The isoelectric points of these variously treated samples increased with decreasing O/Si and with increasing N/Si atomic ratios, as the surfaces transitioned from resembling pure SiO_2 to pure Si_3N_4 .

It was considered that both oxidation and thermal treatment under N_2 might offer interesting advantages for orthopaedic implants due to the observed extreme hydrophilicity. The large negative surface charge at homeostatic pH observed for the as-fabricated Si_3N_4 may contribute to its bacteriostatic and osteointegrative behavior. The significant increase in the surface charge for the oxidized material may lead to an enhancement of these properties over what has already been observed for the as-fabricated material. Further, the surface chemistry of silica is well-understood, lends itself to tailored modification, and has already been shown to be an ideal scaffold for bone on-growth. A material that exhibits the flexibility of silica's surface chemistry with the desirable bulk mechanical properties of dense silicon nitride could be readily engineered and adapted to several implant applications. Thus, this potential for modification of silicon nitride surfaces to enhance cell metabolism and possibly promote faster healing in bone repair devices led to further studies of the effects of surface chemistry of silicon nitride on biological interactions (Pezzotti, 2018, 2019).

Effect of Surface Chemistry of Silicon Nitride on Biological Interactions

Certain bioceramics can release or adsorb molecules that support metabolic chemistry and stimulate cells to replicate and function efficiently. In particular, Pezzotti *et al.* (2017a) cite the promising in vitro performance of Si_3N_4 bioceramics with emphasis on its reciprocity with living cells. The importance of elemental silicon in bone development and the bioactivity of silicate glasses are well known (Jones, 2013). Silicon is directly incorporated into hydroxyapatite by ionic substitution. Nitrogen from amino acids is essential for protein synthesis, bone growth, and tissue repair. Cells assimilate and transform water, carbon dioxide (CO_2), and N-containing species – ammonium (NH_4^+), nitrate (NO_3^-), and di-nitrogen (N_2) – into complex biomolecules. Thus when silicon nitride is used as a biomaterial, these N-containing species are all available for biological interactions.

Pezzotti and co-workers have undertaken a number of studies (Pezzotti *et al.*, 2016, 2017a,b; Pezzotti, 2018) the aims of which were to obtain new insights into the biological interactions between Si_3N_4 , with different surface chemistries, and living cells. As with previous investigations, they varied the parameters of thermal treatments on silicon nitride and observed the modifications of its surface chemistry. The treated ceramics were subjected to (1) in vitro tests to examine the treated surface's interaction with relevant proteins, human cells and nosocomial bacteria and (2) in vivo experiments to examine the performance of the modified surfaces in complex, living systems.

Over a 7 day testing period, the in vitro behavior of osteosarcoma cells in the presence of silicon nitride samples with modified surface chemistry was greatly improved in terms of cell differentiation, attachment, proliferation, and apatite formation (Pezzotti *et al.*, 2016). A post-sintering annealing cycle under a N_2 atmosphere resulted in an atypical surface modification of Si_3N_4 with the formation of some unusual Si–Y–Al–O–N phases. Samples exposed to this annealing treatment produced 40% increase in (hydroxy-)apatite formation when compared with as-fired Si_3N_4 and 100% increase when compared with a biomedical Ti alloy. The enhanced apatite formation was shown to preferentially occur at locations corresponding to the mixture of Si–Y–Al–O–N phases and originated from a high density of positively charged surface groups, including both nitrogen vacancies (V_N^{3+}) and N–N bonds (N^{4+}) formed during annealing.

In a further study (Pezzotti *et al.*, 2017b), two short term intervertebral spinal spacers – a Si_3N_4 cervical implant and a PEEK lumbar device – with comparable in vivo service were retrieved and evaluated. The amount of bone growth within the Si_3N_4 implant was found to be orders of magnitude greater than in the PEEK implant. Spectroscopic analyses, including Raman, XPS and FT-IR, consistently demonstrated an important “chemical fingerprint” for the bone grown by human osteoblasts in the neighborhood of the Si_3N_4 surface. This included a modified form of bony apatite in which $(\text{SiO}_4)^{4-}$ tetrahedra and N^{3-} ions substituted for $(\text{PO}_4)^{3-}$ tetrahedra and OH^- ions, respectively. The availability and release of Si and N atoms at the surface of Si_3N_4 and their favorable biological interaction increases the metabolic activity of osteoblasts, which in turn results in rapid and efficient bone growth. These data suggest that, in contrast to traditional bioinert devices such as PEEK, solid Si_3N_4 stimulates human cells to produce a “chemically modified” bony apatite, and provides local healing at least comparable to synthetic hydroxyapatite and anti-resorptive drugs. This opens the possibility of promoting faster healing in a new generation of high-performance bone repair devices.

Pezzotti (2018) reported that the peculiar surface chemistry of bulk Si_3N_4 bioceramic in an aqueous environment has the potential to reduce implant-associated bacterial infections. Similar to the antibacterial effect exerted by reactive oxygen species (ROS) from TiO_2 , reactive nitrogen species (RNS), such as nitrous oxide (N_2O), nitric oxide (NO), and peroxyxynitrite (OONO) in Si_3N_4 , severely affect bacterial metabolism and lead to their lysis. Functioning as a spontaneous NO donor, the Si_3N_4 surface provides a slow and constant release of such a potent bactericidal agent. A spike in NO concentration was directly monitored in living bacteria after 24 h exposure to Si_3N_4 substrates, which coincided with the beginning of DNA degradation observed by in situ Raman spectroscopy. After 48 h, the DNA of bacteria showed complete destruction on Si_3N_4 . RNS developed on Si_3N_4 substrates were more efficient in inducing bacterial lysis than ROS developed on TiO_2 .

Pezzotti (2019) considers that the use of silicon nitride in biomedical applications has been an “unexpected gift”. While it retains all of its engineered mechanical properties, it has unusual surface chemistry such that when it is immersed in an aqueous environment, slow elution of Si and N from its surface enhances healing of soft and osseous tissue, inhibits bacterial proliferation and even eradicates viruses. He poses the question: “How can this unique bioceramic be both friendly to mammalian cells while concurrently destroying invasive pathogens?” This unparalleled characteristic can be explained by the pH-dependent kinetics of two species – NH_4^+ and NH_3 – both of which are leached from the wet Si_3N_4 surface. A deeper understanding of the chemical interactions of bioceramics with living tissue will ultimately lead to new therapeutic strategies.

Fabrication Techniques

Rahaman and Xiao (2018) have reviewed recent developments in the design, processing, and evaluation of silicon nitride implants for biomedical applications. Si_3N_4 components are manufactured using conventional ceramic fabrication methods, such as die and cold isostatic pressing, injection molding and slip casting. Some of these allow near-net-shape fabrication of complex shapes whereas some often require post-fabrication diamond machining to produce the requisite shape and dimensions which can be costly.

Some biomedical implants may require a composite architecture composed of a dense (outer) region to provide strength to support physiological loads and a porous (inner) region with the requisite porosity and pore size for bone infiltration and integration with host bone. Conventional forming methods are limited in their ability to produce microstructures with a controlled spatial distribution of porosity and the requisite pore size to facilitate osseointegration. In comparison, additive manufacturing techniques such as robocasting can provide better control of the shape and architecture of silicon nitride green parts. Robocasting is a colloidal-based method based on computer-controlled layer-by-layer deposition of a highly concentrated suspension (slurry or paste) through a nozzle of diameter $\sim 100\text{ }\mu\text{m}$ to $\sim 1\text{ mm}$. Thus, additive manufacturing methods could provide a viable route for creating custom orthopaedic implants with the desired shape, architecture, and precise dimensions.

Summary – Silicon Nitride

Silicon nitride has been shown to have very interesting and unique properties. It can be created with a smooth or microrough surface topography, and its surface chemistry can be varied from a silica-rich to a predominantly N-rich composition, which can influence the response of cells, tissues, and bacteria in vivo. Si_3N_4 implants have shown attractive osseointegration and anti-microbial activity in vivo. Commercially, it has been developed for spinal reconstruction devices but its use in orthopaedic applications has so far not been realised commercially. This is due partly to the long and costly process of approval by various regulatory authorities. It should also be noted that silicon nitride requires a different and more costly process for manufacture, i.e., sintering at higher temperatures than oxides and under a nitrogen atmosphere and, with higher hardness, it is more difficult to machine. However, the development of silicon nitride devices in orthopedics is expected to be realised in the near future.

Silicon Carbide

SiC exists in many polymorphic forms called polytypes where the coordination between Si and C is always tetrahedral and the structures differ only in the sequence of identical layers of Si atoms coordinated to four C atoms (Pandey and Krishna, 1975). β -SiC adopts the cubic zinc blende structure whereas the other common polymorphs have a hexagonal structure, related to the Wurtzite crystal structure and, for historical reasons, are collectively referred to as α -SiC. Silicon carbide has been developed as an engineering ceramic with excellent high-temperature strength, good oxidation and thermal shock resistance, high hardness, and low specific weight. Because of its strong covalent bonding character, as with silicon nitride, SiC requires the use of sintering additives and external pressure to enable densification.

Both α - and β -SiC powders can be densified at temperatures of 1850–2000°C with the addition of Al_2O_3 and Y_2O_3 which involves liquid-phase-sintering (Lee and Kim, 1994). With α -SiC, the microstructure consisted of equiaxed SiC grains, whereas with β -SiC, a platelike grain structure resulted from the grain growth associated with the $\beta \rightarrow \alpha$ -SiC phase transformation during sintering. As grain size increased for the sintered SiC from α -SiC powder, fracture toughness increased slightly whereas for the sintered SiC from β -SiC powder, fracture toughness increased significantly which was attributed to crack bridging and crack deflection by the platelike α -SiC grains.

Silicon carbide ceramics have been considered as potential materials for biomedical applications (Rade *et al.*, 2013). SiC showed good wetting properties but bioactivity, estimated on the basis of hydroxyapatite formation in simulated body fluid, was only achieved by surface modification. Much of the literature is concerned with property assessments of SiC rather than biomedical aspects.

Biomorphic SiC can be fabricated by controlled pyrolysis of wood to obtain a carbon scaffold and subsequent reactive infiltration with molten silicon at 1550°C to obtain the silicon carbide scaffold. Through this process, the microstructure of the final SiC product mimics that of the starting material with porosity ranging from 30% to 70% and resembles the cellular microstructure and mechanical characteristics of the bone (González *et al.*, 2003). It can be coated with bioglass for potential implant applications.

Cell morphology, proliferation, and osteogenic activity were successfully evaluated in biomorphic SiC scaffolds with MC3T3-E1 pre-osteoblasts up to 28 days (López-Álvarez *et al.*, 2013). After one day of incubation cells appeared closely attached to the SiC

ceramics with the flattened morphology typical of healthy osteoblasts starting to colonize the pores. On the 7th day of incubation several layers of cells covered the surface without any sign of cytotoxicity. Finally, after 28 days of cell culture micrographs showed a pre-mineralized extracellular matrix with a complex network of filopodia.

One problem facing the medical community today is the lack of biocompatible materials that are also capable of electronic operation. Such devices are currently implemented using silicon technology, which either has to be hermetically sealed so it cannot interact with the body or the material is only stable in vivo for short periods of time. For long term use (for example, permanent implanted devices such as glucose sensors, brain-machine-interface devices) a more robust material that the body does not recognize and reject as a foreign material is needed. Silicon carbide may be just such a material that will allow the development of advanced biomedical devices never thought possible for long-term use in vivo. SiC is a wide-band-gap semiconductor biocompatible material that offers higher power densities and lower energy losses, enabling lighter, more compact and higher efficiency products for biocompatible and long-term in vivo applications ranging from heart stent coatings to neurological implants and sensors (Saddow, 2016).

Carbon in Biomedical Engineering

Jill S Kawalec, College of Podiatric Medicine, Kent State University, Independence, OH, United States

Introduction

Carbons are ubiquitous materials that are easily recognizable in a wide variety of forms, such as graphite and diamond. Each type of carbon has a specific atomic structure and mechanical properties. As carbon is prevalent in all living organisms, it seemed natural to examine the material for potential use in biomedical engineering. It has long been established that medically relevant carbons do not elicit an adverse reaction in the host tissue, and conversely, the host environment does not have a harmful effect on the carbon material.

Carbons were first studied as a biomaterial in the late 1960s, when pyrolytic carbon was used for a component of mechanical heart valve implants. Since then, two other types of carbon have also been used in biomedical applications. Vitreous (glassy) carbon has been used as an electrode material for pacemakers (Beyersdorf *et al.*, 1988), neural implants (Vomero *et al.*, 2019) and glucose biosensors (Castrignanò *et al.*, 2016), to name a few. Also, in the past, vapor-deposited carbon has been coated onto vascular grafts (Aebischer *et al.*, 1988; Bernex *et al.*, 1992).

Pyrolytic carbon has emerged as a material that is extensively used in biomedical engineering. It is also referred to as low temperature isotropic, or LTI carbon. Pyrolytic carbon is a coating that is applied to a substrate, typically graphite. The coating is approximately 0.1–1 mm thick. Pyrolytic carbon has been alloyed with approximately 7% silicon (Si) to enhance the strength and hardness of the material, which improves wear resistance. While the Si-alloyed material is successful in cardiovascular and orthopedic practices, unalloyed pyrolytic carbon is most often used in biomedical applications today.

Structure of Pyrolytic Carbon

Pyrolytic carbon has a crystal structure that is loosely similar to that of graphite. The structure of graphite consists of carbon atoms arranged in planar hexagonal arrays (Bokros, 1977). Strong covalent bonds exist between the atoms in the basal plane. The planar arrays are stacked in an ordered ABAB sequence to produce a hexagonal close-packed crystal lattice. The carbon atoms between adjacent planes are bound by weaker van der Waals bonds (Bokros, 1977; More *et al.*, 2013).

In contrast to graphite, pyrolytic carbon has a turbostratic structure. The basal planes are warped and contain defects, such as missing carbon atoms. The crystallites are relatively small. The layers within the crystallites lie roughly parallel to one another, but the atoms in one layer may have no additional relationship to those in other layers of the same crystallite. The stacking of the planes is haphazard, and thus there is very little order in the direction perpendicular to the planes. This results in higher bonding strengths between the planes, and contributes to enhanced mechanical properties such as fatigue resistance and wear resistance (Bokros, 1977; More *et al.*, 2013; Tian *et al.*, 1993).

Fabrication of Pyrolytic Carbon

Pyrolytic carbon is often deposited as a coating, with a thickness of 0.1–1 mm, onto a graphite substrate (Bellemère, 2018; More *et al.*, 2013) through a process called pyrolysis. During this procedure, ceramic particles are placed into a vertical tube reactor. A flow of inert gas, such as argon, nitrogen or helium, causes the particles to levitate, creating a fluidized bed. The substrate to be coated is added into the fluidized bed, which is then heated to 1500°C. A hydrocarbon gas such as propane or methane is passed through the bed and, due to the high temperature, the hydrocarbon is thermally decomposed, or pyrolyzed. As a result, carbon atoms are deposited onto the substrate, where they coalesce to form the coating (Bellemère, 2018; More *et al.*, 2013).

Mechanical Properties of Pyrolytic Carbon

The mechanical properties of pyrolytic carbon make it an ideal material for medical applications. Its modulus of elasticity ranges from 20 to 29 GPa, which is similar to that of cortical bone (18–20 GPa) (Bellemère, 2018; More *et al.*, 2013). As a result, the carbons are mechanically compatible with bone. The stresses are distributed more equally between carbon and bone while minimizing areas of stress concentration, thus preventing stress shielding and the associated bone weakening and loss.

Pyrolytic carbon is not susceptible to fatigue failure (Bellemère, 2018; Bernex *et al.*, 1992; More *et al.*, 2013). During cyclical testing, the material does not fail at stresses below the fatigue limit. However, at stresses above the fatigue limit, the material fails during the first cycle of loading. Thus, the fatigue limit is equal to the static strength (Beyersdorf *et al.*, 1988; Shim, 1974). The inherent resistance of pyrolytic carbon to fatigue failure is related to the lack of mobile defects in the turbostratic structure of the

materials, which, when present, provide a mechanism for fatigue crack propagation. Because of this behavior, pyrolytic carbon is suitable for use in applications that experience cyclic loads, such as artificial heart valves and joint replacement devices.

The hardness of a material serves as an indication of wear resistance. Materials with higher hardness numbers are more resistant to wear. Pyrolytic carbon has a hardness of 236 DPH (More *et al.*, 2013), and therefore exhibits excellent wear resistance.

Biocompatibility of Pyrolytic Carbon

Carbon, in general, displays good biocompatibility with the human body, as the element is naturally abundant in the biological system. More specifically, pyrolytic carbon possesses excellent biocompatibility in blood, and in soft and hard tissues.

The proper functioning of blood flow through the cardiovascular system depends on a precise balance between blood proteins and cells. Any slight change in this balance can lead to blood coagulation. Most foreign materials, when placed in contact with blood, will induce coagulation. However, pyrolytic carbon has demonstrated good to excellent thromboresistance, and may interact with blood without inducing clot formation (Bokros, 1977). Pyrolytic carbon is a hydrophobic material which promotes protein adsorption, resulting in a protein layer on the surface (Bellemère, 2018). The thromboresistance of pyrolytic carbon is confirmed by many years of success with pyrolytic carbon mechanical heart valve implants.

Pyrolytic carbon also exhibits excellent biocompatibility in both soft and hard tissues. Bone has been shown to grow up to the surface of the material without an intervening fibrous capsule, thus fixation can occur via direct bone apposition. Pyrolytic carbon does not induce a foreign body reaction or inflammatory response in adjacent tissue. Furthermore, it does not elicit a systemic response in the major organs, tissues, blood and urine.

Many materials are inert in the body in bulk form, but in particulate form induce a severe inflammatory reaction. Pyrolytic carbon particles, however, induce a minimal, passive response. Carbon particulates on the order of one micron provoke no inflammatory reaction when injected into the peritoneal cavity and placed surgically into the knee joints of rats (Helbing *et al.*, 1977). The particles migrate from the site of implantation through the lymphatic system and accumulate in the lymph nodes. There is no apparent damage to the lungs, liver, spleen, lymph nodes, or kidneys.

Applications of Biomedical Carbons

Cardiovascular Applications

As a result of excellent thromboresistance and good mechanical properties, carbons have been used in cardiovascular applications, primarily in mechanical heart valves. The heart beats an average of 38 million times a year, and therefore the materials used to fabricate mechanical heart valves must be able to withstand cyclic stress and wear, while minimizing clot formation. Today, over 182,000 heart valves are replaced annually, the majority of which contain pyrolytic carbon components.

In 1969, pyrolytic carbon was first used in artificial heart valves with a caged ball design (Gott *et al.*, 2003). The ball was made of pyrolytic carbon while the cage was composed of titanium. The implant was eventually discontinued when the pyrolytic carbon ball was found to erode the titanium struts. In the early 1970s, non-tilting disc valves with pyrolytic carbon occluders were introduced, however they were also discontinued due to the wear of the fabric covering the titanium housing (Gott *et al.*, 2003). Additionally in the early 1970s, the first mechanical heart valves with a pyrolytic carbon tilting convex disc occluder were created (Gott *et al.*, 2003). Subsequent designs included those in which the disc was contained by prongs or via a guide strut through the center of the disc. Several mechanical valves with pyrolytic carbon tilting disc occluders are currently still in use, including one design in which the housing is also made of pyrolytic carbon. In 1977, the pyrolytic carbon bileaflet valve design, consisting of two semi-circular leaflets, was introduced (Gott *et al.*, 2003). When the leaflets open, a central and two peripheral channels are created for blood flow. The implant was the first mechanical heart valve in which all components (housing and leaflets) were made of pyrolytic carbon. This implant design is the most commonly used for mechanical heart valves (Bloomfield, 2002).

Pyrolytic carbon mechanical valves are widely used for the replacement of the aortic (Saito *et al.*, 2016; Chan *et al.*, 2010; Chambers *et al.*, 2013; Bouchard *et al.*, 2014) and mitral (Saito *et al.*, 2016; Chan *et al.*, 2010; Chambers *et al.*, 2013; Murana *et al.*, 2018; Bouchard *et al.*, 2014) valves. Studies have compared the mortality rate between aortic valve replacement and mitral valve replacement. Early mortality rate (within 30 days of implantation) ranged from 0.9% to 4.4% for aortic valve replacement, and from 2.2% to 7.9% for mitral valve replacement (Saito *et al.*, 2016; Chan *et al.*, 2010; Chambers *et al.*, 2013; Bouchard *et al.*, 2014). Late mortality rate ranged from 16.9% to 30.8% for aortic valve replacement, and from 31.0% to 38.9% for mitral valve replacement (Saito *et al.*, 2016; Bouchard *et al.*, 2014). Furthermore, aortic valve replacement demonstrated a lower valve-related mortality rate (5.2% to 8.8%) compared to that for the mitral valve replacement (11.0% to 12.3%) (Saito *et al.*, 2016; Bouchard *et al.*, 2014). Regarding hemorrhaging, the five-year freedom from bleeding was 93.6% (Chan *et al.*, 2010) and the 30-year freedom from bleeding was 95.6% (Saito *et al.*, 2016) for aortic valve replacement. With respect to mitral valve replacement, the five-year freedom from bleeding was 95.7% (Chan *et al.*, 2010) and the 30-year freedom from bleeding was 93.0% (Saito *et al.*, 2016). Considering blood clotting, the five-year freedom from thromboembolism was 96.5% (Chan *et al.*, 2010) and the 30-year freedom from thromboembolism was 88.6% (Saito *et al.*, 2016) for aortic valve replacement. The five-year freedom from thromboembolism with mitral valve replacement was 97.7% (Chan *et al.*, 2010), while the 30-year freedom from thromboembolism was

79.8% (Saito *et al.*, 2016). In general, while both valve replacements have excellent outcomes at intermediate and long-term follow-up, the aortic valve replacement performs better than the mitral valve replacement.

Pyrolytic carbon bileaflet mechanical valves have also been used for double valve replacements, in which both the aortic and mitral valves are replaced (Saito *et al.*, 2016; Chambers *et al.*, 2013). Long-term studies found that the early mortality rate with a double valve replacement ranged from 3.6% to 4.3% (Saito *et al.*, 2016; Chambers *et al.*, 2013), while the late mortality rate was 35.2% and the valve-related mortality rate was 9.2% (Saito *et al.*, 2016). The linearized late mortality rate was 4.1% per patient-year, while the linearized valve-related rate was 1.8% per patient-year (Chambers *et al.*, 2013). With respect to the incidence of hemorrhage and clotting, the 30-year freedom from excessive bleeding was 90.4%, and the 30-year freedom from thromboembolism was 80.8%. These values were significantly less than with aortic valve replacement alone, at $p < 0.05$ and $p < 0.0001$, respectively (Saito *et al.*, 2016). Thus, double valve replacement demonstrated very good outcomes but did not perform as well as single valve replacement.

Although uncommon, pyrolytic carbon bileaflet valves have been used for the replacement of the tricuspid valve (Zhu *et al.*, 2018). In this study of 265 cases, thrombosis of the valve was noted in 3.8% of the replacements, however in the majority of the cases the cause was due to the inappropriate use of anticoagulants. Three implants had to be replaced due to thrombosis. The survival rate was 89.2% after five years and 86.6% after 10 years, though only two deaths were associated with valve complications. Overall, the long-term outcomes for replacement of the tricuspid valve with a pyrolytic carbon bileaflet valve were good.

Orthopedic Applications

Hand and wrist implants

Pyrolytic carbon implants have been used extensively in the replacement of the small joints of the hand and wrist. The primary reason for the replacement of these joints is arthritis, although trauma can result in the placement of an implant. The proximal interphalangeal (PIP) joint of the hand is the third most common site for osteoarthritis, and when conservative treatments are no longer effective, surgical intervention includes arthrodesis or arthroplasty. While the gold standard for PIP joint arthroplasty is replacement with a silicone implant, pyrolytic carbon prostheses have increasingly been used. The implant is a two-component semi-constrained device. The proximal component is bicondylar in design, while the distal component has two concave surfaces to articulate against the proximal component. The implant is press-fit and allows for bone growth up to the implant.

Clinical studies on the use of pyrolytic carbon PIP implants have demonstrated that, in general, patients experience a significant decrease in pain both at rest and during activity at medium-term and long-term follow-up (Wagner *et al.*, 2018; Wijk *et al.*, 2010; Daecke *et al.*, 2012; Chung *et al.*, 2009; Ono *et al.*, 2012; Herren *et al.*, 2006; Tagil *et al.*, 2014; Watts *et al.*, 2012; Reissner *et al.*, 2014; Mashhadi *et al.*, 2012; Sweets and Stern, 2011; Bravo *et al.*, 2007; Tuttle and Stern, 2006; Adams *et al.*, 2012). Additionally, there was general patient satisfaction with the outcomes (Wijk *et al.*, 2010; Chung *et al.*, 2009; Ono *et al.*, 2012; Tagil *et al.*, 2014; Desai *et al.*, 2014; Sweets and Stern, 2011; Tuttle and Stern, 2006) and range of motion was unchanged in the majority of the studies (Wagner *et al.*, 2018; Wijk *et al.*, 2010; Daecke *et al.*, 2012; Chung *et al.*, 2009; Ono *et al.*, 2012; Nunley *et al.*, 2016; Branam *et al.*, 2007; Herren *et al.*, 2006; Tagil *et al.*, 2014; Dickson *et al.*, 2015b; Watts *et al.*, 2012; Mashhadi *et al.*, 2012; Bravo *et al.*, 2007; Tuttle and Stern, 2006). Sweets and Stern (2011), however, found that the range of motion of the PIP joint significantly improved from pre-operative measurements to approximately one-year post-operatively, but then decreased to below pre-operative values at a mean final follow-up of 55 months. With respect to grip strength, most of the research suggests that, after pyrolytic carbon PIP joint arthroplasty, there is no change in strength (Wagner *et al.*, 2018; Wijk *et al.*, 2010; Daecke *et al.*, 2012; Chung *et al.*, 2009; Ono *et al.*, 2012; Nunley *et al.*, 2016; Branam *et al.*, 2007; Tagil *et al.*, 2014; Bravo *et al.*, 2007).

Complication rates associated with pyrolytic carbon PIP joint arthroplasty are reportedly higher than those related to silicone PIP implants (Squiteri and Chung, 2008; Chan *et al.*, 2013). Common complications include loosening of the implant (Daecke *et al.*, 2012; Nunley *et al.*, 2016; Branam *et al.*, 2007; Herren *et al.*, 2006; Tagil *et al.*, 2014; Dickson *et al.*, 2015b; Watts *et al.*, 2012; Sweets and Stern, 2011; Bravo *et al.*, 2007; Tuttle and Stern, 2006; Adams *et al.*, 2012), dislocation of the implant (Daecke *et al.*, 2012; Chung *et al.*, 2009; Ono *et al.*, 2012; Branam *et al.*, 2007; Sweets and Stern, 2011; Tuttle and Stern, 2006), joint stiffness (Dickson *et al.*, 2015b; Watts *et al.*, 2012; Desai *et al.*, 2014), joint instability (Dickson *et al.*, 2015b; Watts *et al.*, 2012; Mashhadi *et al.*, 2012; Bravo *et al.*, 2007) and persistent pain (Wijk *et al.*, 2010; Nunley *et al.*, 2016; Tagil *et al.*, 2014; Bravo *et al.*, 2007). Squeaking of the implant has been reported (Chung *et al.*, 2009; Ono *et al.*, 2012; Branam *et al.*, 2007; Dickson *et al.*, 2015b; Watts *et al.*, 2012; Mashhadi *et al.*, 2012; Desai *et al.*, 2014; Sweets and Stern, 2011; Tuttle and Stern, 2006), however this did not appear to affect the performance of the device and patient satisfaction. Reviews of the literature indicate that there is no evidence to replace the silicone PIP implant with a pyrolytic device as the gold standard for treatment (Squiteri and Chung, 2008; Chan *et al.*, 2013).

Pyrolytic carbon implants have also been used to replace the metacarpophalangeal (MCP) joint of the hand. An early clinical study of the use of pyrolytic carbon to replace this joint demonstrated that at long-term follow-up (average 11.7 years post-operative), range of motion (ROM) was increased by an average of 13 degrees with no resorption of bone (Cook *et al.*, 1999). Pyrolytic carbon was found to be a suitable material for the replacement of the MCP joint. Since then, further clinical studies have shown that, in general, patients experience a decrease in pain (Nunez and Citron, 2005; Parker *et al.*, 2007; Parker *et al.*, 2006; Dickson *et al.*, 2015a; Aujla *et al.*, 2017) at both medium-term and long-term follow-up. Many of the studies also indicated an increase in pinch and grip strengths (Nunez and Citron, 2005; Parker *et al.*, 2007; Parker *et al.*, 2006; Wall and Stern, 2013; Simpson-White and Chojnowski, 2014; Dickson *et al.*, 2015a), and an increased satisfaction with functionality and appearance (Nunez and Citron, 2005; Parker *et al.*, 2007, 2006; Wall and Stern, 2013; Simpson-White and Chojnowski, 2014; Dickson *et al.*, 2015a; Aujla *et al.*, 2017). The literature presents

conflicting data regarding change in ROM after MCP joint replacement with pyrolytic carbon implants, but increases in ROM were more often observed at longer follow-up periods (Wall and Stern, 2013; Simpson-White and Chojnowski, 2014; Aujla *et al.*, 2017). Complications associated with pyrolytic carbon MCP joint implants include extensor tendon pathology (Parker *et al.*, 2007, 2006; Wall and Stern, 2013; Houdek *et al.*, 2015), stiffness (Parker *et al.*, 2007; Wall and Stern, 2013; Houdek *et al.*, 2015; Dickson *et al.*, 2015a), subluxation or dislocation of the implant (Parker *et al.*, 2007, 2006; Dickson *et al.*, 2015a), and implant fracture (Simpson-White and Chojnowski, 2014; Houdek *et al.*, 2015; Dickson *et al.*, 2015a).

The use of pyrolytic carbon implants to replace the trapeziometacarpal joint in the wrist has been explored. Hemiarthroplasty implants have been used in which the proximal aspect of the first metacarpal is replaced (Vitale *et al.*, 2017; Martinez de Aragon *et al.*, 2009; Caudwell *et al.*, 2018), however long-term follow-up has not been conducted. Medium-term studies have shown that there is an increase in grip strength (Vitale *et al.*, 2017; Martinez de Aragon *et al.*, 2009), radial abduction (Vitale *et al.*, 2017), and oppositional and appositional pinch (Vitale *et al.*, 2017; Martinez de Aragon *et al.*, 2009). However, revision surgery can result from subluxation, displacement or fracture of the implant (Vitale *et al.*, 2017; Martinez de Aragon *et al.*, 2009; Caudwell *et al.*, 2018), loosening (Martinez de Aragon *et al.*, 2009), pain (Martinez de Aragon *et al.*, 2009), and bone fracture (Martinez de Aragon *et al.*, 2009). At a mean follow-up of 6.5 years, there was no significant difference in grip or pinch strength between the operated and contralateral sides (Caudwell *et al.*, 2018). Furthermore, when compared to a suspensionplasty procedure, there was a significantly higher number of major complications and joint revision surgery when pyrolytic carbon hemiarthroplasty implants were used to treat arthritis of the joint (Vitale *et al.*, 2017). More research on pyrolytic carbon hemiarthroplasty implants for the replacement of the trapeziometacarpal joint is necessary.

Pyrolytic carbon interposition implants have also been studied for the treatment of arthritis of the trapeziometacarpal joint (Colgate-Stone *et al.*, 2011; Szalay *et al.*, 2013; Barrera-Ochoa *et al.*, 2014; Agout *et al.*, 2016). In this case, the implant is used to replace the trapezium after a trapeziectomy. While the implant results in a significant decrease in symptoms and pain (Colgate-Stone *et al.*, 2011), and patients are satisfied with the outcomes (Barrera-Ochoa *et al.*, 2014), complications such as implant dislocation and persistent pain do occur (Colgate-Stone *et al.*, 2011; Szalay *et al.*, 2013; Barrera-Ochoa *et al.*, 2014). In the early stages of investigating pyrolytic carbon as an interposition implant to replace the trapezium, the superiority of the pyrolytic carbon implant was not able to be proved. Given the high cost of the implant, high learning curve for the surgical technique and extended surgery time, surgeons at the time discontinued the use of the implant in their practice (Colgate-Stone *et al.*, 2011; Szalay *et al.*, 2013). However, a study that looked at the interposition implant with a minimum 10-year follow-up period (average 10.5 years) found that grip strength, key pinch strength, and pain levels improved considerably, and that the vast majority of patients were satisfied with the device (Agout *et al.*, 2016).

Although less frequently, pyrolytic carbon implants have been used to replace other small bones or joints in the wrist. Early results from the replacement of the scaphotrapeziotrapezoid joint with a pyrocarbon interposition implant, either circular (Pegoli *et al.*, 2006) or rectangular (Gauthier *et al.*, 2017) in shape, indicate improvement in pain, symptoms, and strength. However, longer-term studies with a greater sample size are needed. Preliminary studies on the replacement of the radiocarpal and midcarpal joints with an olive-shaped pyrocarbon interposition implant as a primary or revision procedure have been reported (Daruwalla *et al.*, 2012; Bellemère *et al.*, 2012a,b; Pierrart *et al.*, 2012). In the procedure, the implant replaces the lunate, proximal two-thirds of the scaphoid and a small section of the head of the capitate. Early results from these studies indicate high satisfaction with the device and considerable improvement in pain and function, but little, if any, change in mobility and grip strength. Further studies with a larger sample size and longer follow-up are warranted on this implant. Finally, an ovoid-shaped pyrocarbon interposition implant with adaptive mobility that occurs with motion of the wrist has been studied for the replacement of the proximal pole of the scaphoid in cases of nonunion due to avascular necrosis (Gras *et al.*, 2012; Aribert *et al.*, 2019), scaphoid nonunion advanced collapse (SNAC) wrist (Daruwalla *et al.*, 2013; Santos *et al.*, 2018; Aribert *et al.*, 2019), and radioscapoid osteoarthritis (Daruwalla *et al.*, 2013; Aribert *et al.*, 2019). With follow-up ranging from an average 1.6–10 years, the results are encouraging. Improvement in pain (Gras *et al.*, 2012; Daruwalla *et al.*, 2013; Santos *et al.*, 2018; Aribert *et al.*, 2019) and function (Gras *et al.*, 2012; Daruwalla *et al.*, 2013; Aribert *et al.*, 2019) were reported. In long-term follow-up studies, an increase in grip strength was noted (Gras *et al.*, 2012; Aribert *et al.*, 2019), however the grip strength was less than that on the contralateral side at shorter follow-up periods (Daruwalla *et al.*, 2013; Santos *et al.*, 2018).

Shoulder implants

The pyrolytic carbon interposition shoulder arthroplasty (PISA) is a relatively new implant to replace the humeral head. It consists of a graphite sphere coated with pyrolytic carbon, and is placed freely within a cavity created in the proximal aspect of the humerus. It was developed in response to the poor performance of metallic humeral heads of hemi-shoulder arthroplasties that articulate with the glenoid cavity. This innovative implant was used in a study of 61 patients who presented with primary osteoarthritis, avascular necrosis, or post-instability or post-fracture secondary osteoarthritis (Garret *et al.*, 2017). At a mean follow-up of 26.8 months, improvements in pain, activity, mobility and strength were noted. However, radius of curvature and the free positioning of the implant were noted as potential causes of failure. A longer term study (mean follow-up of 42.8 months) using the same implant was conducted in 10 patients who presented with advanced collapse of the humeral head after post-fracture avascular necrosis (Hudek *et al.*, 2017). Patient satisfaction was high and the function of the shoulder was excellent. The study found that the collapse of the humeral head was a good indication for the use of PISA implants. Studies with longer follow-up periods and greater sample sizes are needed to fully assess the success of the implant.

A hemi-shoulder arthroplasty was evaluated for the replacement of the humeral head (Garret *et al.*, 2019). The implant consisted of a pyrolytic carbon humeral head on a cobalt-chromium taper that connected to a convertible humeral stem. The study of 61 patients included 37 individuals with primary osteoarthritis, 11 with osteonecrosis, 11 with secondary osteoarthritis and two with rheumatoid arthritis. With a mean follow-up of 25.9 months, there was improvement in both pain and activity level. However, the outcomes were based on the etiology of the shoulder pathology. Replacement due to atraumatic osteonecrosis and post-instability secondary osteoarthritis produced satisfactory results, while those for post-traumatic osteonecrosis and post-traumatic secondary osteoarthritis resulted in poor outcomes. Patients with rheumatoid arthritis were satisfied with the surgery, although the outcomes were not exceptional. More research is needed on this implant.

Carbon Fibers

Carbon fibers are lightweight, high strength, flexible, biocompatible and chemically stable. They are produced by pyrolyzing organic precursor fibers such as pitch, polyacrylonitrile (PAN) and rayon (Migliaresi, 2013). The fibers can be used alone or as part of a composite material. Composites are a combination of two or more materials that, when used together, significantly improve the performance of the material. They consist of a matrix material and fiber material, which can be the same or different materials. Carbon fiber reinforced polymers have been used in cardiovascular, spinal, dental and orthopedic applications.

Carbon fiber reinforced polyetheretherketone (CFR-PEEK) is a material that is used frequently in biomedical applications. PEEK is a polymer with excellent biocompatibility, high strength, chemical resistance and a modulus of elasticity similar to that of cortical bone. The addition of carbon fibers to PEEK further increases the mechanical strength of the material. The type of carbon fiber has an effect on the static and fatigue behavior of CFR-PEEK (Bonnheim *et al.*, 2019). Composites with PAN carbon fibers had a significantly higher modulus of elasticity and ultimate tensile strength compared to those with pitch carbon fibers. For both types of fibers, these properties were significantly greater than that for unreinforced PEEK. Additionally, both types of CFR-PEEK composites experienced brittle failure, while PEEK alone underwent some degree of plastic deformation before failure. With respect to fatigue behavior, PAN CFR-PEEK was more resistant to fatigue crack propagation, compared to pitch CFR-PEEK and PEEK alone.

Common orthopedic applications of CFR-PEEK include fracture fixation plates, such as those used for the repair of distal fibula fractures (Wilson *et al.*, 2016) and distal radius fractures (Mugnai *et al.*, 2018; Gallagher *et al.*, 2019). The material has also been investigated for use as intramedullary nails for musculoskeletal tumors (Piccioli *et al.*, 2017) and in total knee arthroplasty (Koh *et al.*, 2019). Spinal applications include pedicle screws for spinal fusion (Lindtner *et al.*, 2018). Finally, CFR-PEEK has been investigated for use in dental applications such as abutment screws (Neumann *et al.*, 2014; Schwitalla *et al.*, 2018).

Conclusion

Carbon has been shown to be mechanically and chemically suitable for use in the human body. Both pyrolytic carbon and carbon fibers have been widely used in biomedical applications. As fabrication techniques are continuously refined and improved, the properties of the material will be enhanced and new applications will be explored.

Yttria-Stabilized Zirconia as a Biomaterial: From Orthopedic Towards Dental Applications

Helen Reveron and Jérôme Chevalier, University of Lyon, Villeurbanne Cedex, France

© 2021 Elsevier Inc. All rights reserved.

Introduction

Zirconia was introduced in orthopedics in 1984, in the form of a magnesia-stabilized ceramic (Mg-PSZ for *Partially Stabilized Zirconia*) to answer the problem of alumina brittleness and the risk of failure of femoral heads in total hip replacement (THR) procedures. Mainly USA and Australia developed a Mg-PSZ orthopedic zirconia, which has never been used in large-scale clinical trials. In the late 1980s, yttria-stabilized zirconia containing 3 mol% of Y_2O_3 (3Y-TZP for *Tetragonal Zirconia Polycrystal*) rapidly took its place in the orthopedic field, especially due to its higher strength (more than 1000 MPa, i.e., at least twice that of Mg-PSZ). The impressive strength of 3Y-TZP compared to Mg-PSZ results from the microstructural refinement (typically tetragonal grains of size <500 nm compared to 30–40 μm for the cubic grains of Mg-PSZ) because 3Y-TZP ceramics can be sintered at lower temperatures (1400°C versus 1800°C for Mg-PSZ). As will be discussed below, 3Y-TZP zirconia also takes advantage of phase transformation toughening, which increases its crack propagation resistance. From the early 1990s to 2002, more than 600,000 hip femoral heads made of 3Y-TZP were implanted worldwide. The most important manufacturers were Saint Gobain Desmarquest (SGD) in France, Kyocera in Japan, Metoxit in Switzerland and Morgan Technical Ceramics in UK. At that time, biomedical grade 3Y-TZP femoral heads were considered as the most promising alternative to alumina for THR.

The main toughening mechanism in stabilized zirconia is the stress-induced tetragonal-to-monoclinic (*t-m*) phase transformation. Briefly and schematically, at the crack-tip, the transformation of the metastable tetragonal phase to the stable monoclinic one is accompanied by a lattice expansion that induces compressive stresses, hindering the crack propagation. At a macroscopic level, this results in an apparent increase of the toughness (K_{IC}) of the ceramic material. Therefore, the toughness of 3Y-TZP is about twice that of alumina (5–8 MPa $\sqrt{m}$ versus 3–4 MPa $\sqrt{m}$, respectively). Due to these major advantages, 3Y-TZP allowed producing smaller femoral heads that were not possible to manufacture with alumina (e.g., 22 mm in diameter) and the development of knee prostheses or hip resurfacing implants. However, from the early 1990s some critical points regarding 3Y-TZP began to be reported, such as its potential radioactivity, the negative effect of steam sterilization procedures on the surface roughness and its questionable stability in contact with water or body fluids. This last fact, better known as Low Temperature Degradation (LTD) or “aging” led to 3Y-TZP abandon in the orthopedic field in the early 2000s. To date, numerous reports show that LTD was the responsible for a series of 3Y-TZP femoral heads fractures (Chevalier, 2006; Chevalier *et al.*, 2009).

As regards the zirconia radioactivity issues, they were induced by the fact that zirconia oxide (ZrO_2 or Baddeleyite) is always found associated to other minerals and natural radionuclides (uranium, radium and thorium). Even if during the processing of the powder such elements are eliminated, the level of purification depends on the powder manufacturer. As some special zirconia powders used as radiopacifier in PMMA cements showed significant radioactive impurities, the competition between alumina and zirconia powder producers strongly stimulated the controversy for a while until other works demonstrated that zirconia ceramics made from highly purified powders exhibited radioactivity levels much below the natural background (Piconi and Maccauro, 1999). Today, international standards specify radioactivity limits of Y-TZP ceramics used for implants to below 200 Bq/Kg (International Organization for Standardization, 2016a). Current developed pure Y-TZP powders show values of 20–50 Bq/Kg, which is clearly below this benchmark.

The most relevant problem remains the stability of zirconia in the presence of water or body fluids, a matter that has caused concern in the orthopedic field, when negative effects of sterilization or premature failures started to be reported. The degradation of zirconia ceramics became well known in the ceramic community after the initial studies of Kobayashi (Kobayashi *et al.*, 1981), who discovered a serious limitation of Y-TZP ceramics for applications at temperatures close to 250°C. During aging or LTD, a spontaneous tetragonal to monoclinic (*t-m*) zirconia phase transformation of grains on any surface in contact with water, water vapor, or body fluid occurs. It means that no external applied stress is needed to start the process. This transformation of surface grains is accompanied by a volume expansion of 3–5 vol% leading to surface-roughening, grain-pull-out and microcracking. 3Y-TZP aging was first thought to be very limited and well-controlled near the ambient temperature. However, in 1997 the US Food and Drug Administration (FDA) reported on the negative effect of steam sterilization procedures applied in zirconia implants (134°C, 2 bars pressure) on their surface roughness. This sterilization procedure is since then forbidden for zirconia. More importantly, in 2001, the FDA announced that firms distributing orthopedic implants were recalling series of Prozyr® 3Y-TZP ball heads made by SGD (Evreux, France). In fact, hundreds of femoral heads failed in recently-implanted patients. The origin of the failures was later related to an accelerated *t-m* phase transformation that occurred in only certain batches. Even though limited in numbers and duration, the production of zirconia femoral heads declined by 90% between 2001 and 2002 and never recovered. This failure episode had a strong negative impact on the use of yttria-stabilized zirconia in orthopedics. Since then, monolithic 3Y-TZP was abandoned in this area, for the benefit of alumina-matrix composites (e.g., Biolox Delta®), which roughly speaking combine the stability of the alumina matrix and a reinforcement by dispersed zirconia grains (very often yttria-stabilized). The same 3Y-TZP ceramic, in which further powder improvements were made to achieve a better aging resistance, as it

is the case with some alumina addition (e.g., zirconia Tosoh E-grades), has become a successful dental material, for the manufacturing of implants and external restorations (crowns, bridges and dentures by CAD-CAM processing of pre-sintered blanks).

“Pro- orthopedic or biomedical zirconia” supporters claim that only 3Y-TZP allows specific designs of implants that would fail with more brittle alumina and composites. They also rightly claim that the 3Y-TZP femoral heads failure rate before 2001 was exceptionally low and that its aging sensitivity can be controlled by a careful monitoring of the processing (powder synthesis, shaping, sintering and post-treatment steps) and/or composition. The “con- orthopedic or biomedical zirconia” advocates, and they are to a certain extent also right, claim that it is unsatisfactory to implant an “unstable” material in the body. Around the mid-2000s, the available clinical retrieval studies did not fully assess this issue. Moreover, their results were somewhat controversial: some results showed excellent behavior of some femoral heads after several years in-vivo, while others showed enhanced roughening associated with severe wear and osteolysis around the implant (Clarke *et al.*, 2003). The aim of this update is therefore to describe based on recent factual knowledge, the major advantages (i.e., crack resistance) and drawbacks (i.e., aging resistance) of yttria-stabilized zirconia ceramics to understand its behavior and why it was abandoned in orthopedics, but immediately introduced in the dental field. Particular emphasis is given to the phase-transformation toughening, the aging phenomenon and the optical properties because they remain the critical points for the future of zirconia in dentistry and in some other niche biomedical applications.

After this introduction, the chapter is divided in three additional sections, a general discussion and some concluding remarks. Section “Main Features of Yttria-Stabilized Zirconia” provides an overview of the key chemical, physical and mechanical properties of Y-TZP. Section “Aging Process and its Consequence on Zirconia-Based Biomedical Implants” shows the nature and importance of LTD in the field of biomedical ceramics. Section “Optical Properties of Yttria-Stabilized Zirconia” analyzes the optical properties of yttria-stabilized zirconia and the impact of novel rich-yttria composition (stabilizer and dopants) on the mechanical resistance and aging. The fifth section discusses the past, the present and the future of biomedical-grade zirconia and ends with a brief conclusion.

Main Features of Yttria-Stabilized Zirconia

Zirconia is a well-known polymorph that occurs in three crystallographic forms: monoclinic (m), tetragonal (t) and cubic (c), at ambient pressure. As shown in Fig. 1, pure zirconia is monoclinic at ambient temperature and pressure. This phase is stable up to 1170°C. Above this temperature, it transforms to the tetragonal phase and then to the cubic one at 2370°C. The cubic phase is stable up to the melting point of 2680°C.

As zirconia products are usually sintered in the 1350–1550°C range, a reverse t–m transformation of the sintered bodies (if made of pure zirconia) occurs during cooling. As pointed out earlier, the t–m transformation is associated with a volume expansion of 3–5%. This inevitably leads to large stresses and cracking upon cooling from the sintering temperature, which prohibits the use of pure zirconia in manufacturing dense products (unless they would be sintered at temperatures lower than 1170°C by non-conventional processes). In order to overcome this problem, additives such as calcia (CaO), magnesia (MgO), yttria (Y₂O₃) or ceria (CeO₂) must be added to zirconia to preserve the material in either the tetragonal (t) or the cubic (c) phase after cooling to room temperature. Biomedical grade zirconia is usually stabilized with 3 mol% Y₂O₃ and its requirements such density (> 6 g/cm³) and grain size (< 0.6 μm) are reported by standards (International Organization for Standardization, 2016a). The addition of stabilizers, here 3 mol% of yttria, maintains the t phase at ambient temperature, therefore in a metastable state. Today, 3 mol% yttria-stabilized zirconia (3Y-TZP) is the most commonly manufactured powder in the ZrO₂-Y₂O₃ system for biomedical use. However, due to the growing interest in using yttria-stabilized zirconia in dental restorations, newer Y-rich zirconia generations (4Y, 5Y, etc.) have been also produced industrially.

Most of the properties of Y-TZP ceramics can be predicted from the ZrO₂-Y₂O₃ equilibrium phase diagram shown in Fig. 1. After sintering, 3Y-TZP is very often described as fully tetragonal zirconia. However, depending on the sintering conditions (temperature and time), it rather consists of a mixture of yttria-poor t and yttria-rich c phases. The phase diagram gives the composition and content at the equilibrium at high temperature (lever rule). After cooling, the t + c phases can be retained. However, again, the phase diagram shows that the metastable t phase will have the tendency to go back to the m stable state. In other words, the reverse t–m transformation is expected to occur at ambient temperature if the energy-barrier for the t–m transformation is lowered. This will depend on the microstructure (mainly on grain size and phase content) and on external parameters, e.g., external applied stresses or environment.

The T–M Phase Transformation

Solid-state phase transformations can be classified as diffusional (so called “civilian”) and diffusionless (so-called “military” or martensitic) depending on the mechanism by which transformation takes place. Martensitic transformations were first described in steels and then in shape memory alloys. There are considered as diffusionless as the movement of each atom involved in the transformation is less than one interatomic spacing, i.e., these transformations do not require long-range movements of atoms. Because of its key role on the mechanical behavior of zirconia, the most studied zirconia phase transformation is the t–m martensitic phase change. This transformation can be induced by a change in the temperature (i.e., during cooling) or by the action of a mechanical stress over the metastable tetragonal phase (case of stabilized zirconia). The t–m transformation temperatures and stresses are mainly dependent on zirconia composition and grain sizes, but can also be affected by other factors such as internal residual stresses. The t–m transformation is reversible and exhibits

Fig. 1 $\text{Y}_2\text{O}_3\text{-ZrO}_2$ equilibrium phase diagram. The vertical blue line represents the composition of 3Y-TZP. The dashed blue horizontal line shows the composition of 3Y-TZP ceramics (t + c phases) at high temperature. Adapted from Scott, H.G., 1975. Phase relationships in the $\text{ZrO}_2\text{-Y}_2\text{O}_3$ system. *Journal of Materials Science* 10, 1527.

hysteresis, in other words the t-m transformation takes place at lower temperature than the m-t one (Bansal and Heuer, 1972). In pure zirconia, the m-t transformation occurs at 1170°C during heating, while the reverse t-m transformation begins at 950°C upon cooling. The stabilization of zirconia with yttria shifts the hysteresis cycle to lower temperatures so the t-m transformation occurs below the ambient temperature for a bulk 3Y-TZP. As the transformation takes place by a cooperative movement of a large number of atoms (shear process) without atomic diffusion, it can occur at any temperature and keeping the same chemical composition. The velocity of the transformation may reach that of sound in the solid. A further consequence of the diffusionless nature of the martensitic transformation is that the change in crystal structure is achieved by a homogeneous deformation of the parent phase on particular crystallographic planes and directions. Macroscopically, the transformation is easily localized because the shape of the transformed region changes, the strain being a combination of shear and dilatational, parallel and normal to the habit plane as described in Fig. 2.

Generally, martensitic transformations lead to less volume change as compared to the shear components. In zirconia, the shear strain is about 0.15–0.17 and the volume change (dilatational strain) near 0.05 (i.e., 5%) (Deville *et al.*, 2004). The t-m zirconia phase transformation leads, therefore, to shear strain and significant volume increase. In metastable zirconia and especially in 3Y-TZP, the t-m transformation can occur in the bulk or at the surface of the material. In the bulk, when induced by applied stresses, the transformation leads to the positive effect of toughening since the localized t-m transformation hinders the propagation of cracks. At the surface, especially in contact with water or body fluids, the spontaneous transformation leads to the negative effect of aging (i.e., increased roughness and microcracking).

Toughening Mechanism in Transformable Zirconia

The metastable nature of tetragonal grains was the basis for the development of zirconia as a “tough” ceramic in the 1970s and 1980s. Garvie *et al.* (1975) showed in their famous paper “Ceramic steel?” that the mechanical strength of zirconia was improved

Fig. 2 Schematic representation of habit plane and shape strain for a martensitic transformation.

Fig. 3 Schematic drawing of the transformation zone around a propagating crack, leading to compressive stresses and subsequent shielding stress intensity factor.

by the t-m transformation that takes place around a propagating crack. The large stresses appearing around a crack lead to the t-m transformation ("process zone"). When a crack propagates, the stress field at the crack tip associated with the volume expansion due to the transformation (compressive stresses) acts against the tensile applied stress field, shielding the crack propagation as illustrated in **Fig. 3**. This t-m phase transformation, usually triggered by shear and/or hydrostatic tensile stresses, leads to a significant increase of the strength due to the increase of the work of fracture.

Transformation toughening was first described in steels showing a TRIP effect (TRIP for *Transformation-Induced-Plasticity*) and wear resistant cast irons (Gerberich *et al.*, 1968). McMeeking and Evans (1982) developed modeling of phase-transformation

toughening in brittle materials at the beginning of the 1980s. Giving a comprehensive review of toughening mechanism is beyond the scope of this chapter. The interested reader may refer to the book “Transformation Toughening of Ceramics” (Green *et al.*, 1989).

The stress-induced t-m phase transformation leads to a shielding K_{Ish} of the applied stress intensity factor K_I . This means that the real stress intensity factor at the crack-tip $K_{I_{tip}}$ is lower than that applied by the external forces, according to

$$K_{I_{tip}} = K_I - K_{Ish} \quad (1)$$

So, the higher the applied stress intensity factor, the higher the shielding stress intensity factor due to the phase transformation, as confirmed experimentally on 3Y-TZP ceramics (Chevalier *et al.*, 1999a). The toughening capability of a given zirconia depends on the critical local stress leading to t-m phase transformation (σ_m^c). The microstructure and composition will play a major role on transformation toughening, since σ_m^c mainly depends on the grain size and the nature and amount of phase stabilizer. Some studies report that about 70%–80% of the applied stress intensity factor is actually reduced at the crack-tip with grain size ranging between 0.5 and 1 μm . The variation of the toughness in biomedical grade 3Y-TZP ceramics ranges from 5 to 8 $\text{MPa}\sqrt{\text{m}}$ for grain sizes of 0.3–1.2 μm (above 1.2 μm , 3Y-TZP is no longer stable). As discussed earlier, typical biomedical alumina exhibits lower toughness values (3–4 $\text{MPa}\sqrt{\text{m}}$) and this was one of the reason for introducing 3Y-TZP ceramics in orthopedics, so to overcome the problem of alumina brittleness.

Today it is well known that ceramic materials are susceptible to slow crack propagation at K_I values under K_{IC} . This behavior is mainly observed in oxide ceramics, for which ionic bonds can react with water at the crack tip. The slow-crack propagation depends on the applied load but can also be sensitive to the environment (atmosphere, chemical species), the temperature and other variables. That means that under “appropriate or specific” conditions, cracks can grow at relatively low stresses. Since it is impossible to completely avoid introducing imperfections and microcracks during the processing of bioceramics, cracks may grow in a slow manner before causing catastrophic failure, without any warning signal. All the aspects of slow crack growth (SCG) in ceramics are covered in the book by Lawn (1993).

As a general trend, slow crack growth is described based on a V (crack velocity) versus K_I (stress intensity factor) diagram. Slow crack growth in ceramics is attributed to stress-assisted corrosion at the crack-tip, or any pre-existing defect in the material. It is indeed the combined effect of high stresses at the crack-tip and the presence of water or body fluid molecules, which reduce surface energy at the crack-tip, thus inducing crack propagation in a slow manner. Over the years, the presence of a threshold in the stress intensity factor (K_{I0}), under which no crack propagation occurs, has been the subject of important research in the ceramic field. The threshold corresponds to crack equilibrium with a null crack velocity, thus propagation does not occur below this. For ceramic joint prostheses, this threshold determines a safety range of use. Above the threshold K_{I0} , three stages are generally observed in oxide ceramics. Each stage can be fitted by a phenomenological power-law relation, in the form

$$V = A \cdot K_I^n \quad (2)$$

where A and n are the slow crack growth parameters associated with the material and the environment conditions. Fig. 4 represents the V – K_I curves of biomedical grade alumina and zirconia ceramics.

Region I depends strongly on external variables, applied stress, temperature, and chemical concentration. In this region, the environmental species react with the ceramic bonds in the crack front-tip. This region is therefore reaction-rate controlled. Region II is insensitive to applied stress, suggesting a transport process in which the active environmental species are increasingly unable to keep pace with the crack front tip as K_I increases. This region depends on the diffusion of the corrosive species from the environment to the crack-tip. Region III is associated with fast fracture and then with K_{IC} . The toughness (K_{IC}) and threshold (K_{I0}) of zirconia are superior to that of alumina. The difference in crack resistance is, however, larger for large stress intensity factors, since the larger the applied K_I the larger the reinforcement. The higher crack resistance of zirconia, compared to alumina, associated with a lower grain size (typically 0.5 μm for zirconia, 2 μm for alumina) leads to a significant increase of the strength. For example, 3Y-TZP strength values as high as 2 GPa have been reported, compared to 600 MPa for alumina.

Phase Transformation by Grinding

In transformable zirconia ceramics such as 3Y-TZP, surface grinding or polishing is sufficient to induce t–m transformation on the surface. This transformation generates a thin surface layer of monoclinic phase, which places the surface of the material in a compressive state. The thickness and features of this layer depends mainly on the severity of the surface treatment, but also on the grain size and composition of the ceramic. It can reach a few tens of microns for surfaces machined under “severe” conditions, with compressive stresses of hundreds of MPa. For example, in 3Y-TZP ceramics (grain size 320 nm), grinding with water at 300 rpm and 80 μm disk produced three different transformed layers (Minguella *et al.*, 2020). A top layer of 300 nm depth containing in-situ recrystallized nano-grains of 10–20 nm in size and microcracks extending parallel to the surface, a second region of $\sim 1 \mu\text{m}$ depth made of plastically deformed grains in a direction parallel to the surface and finally, a layer of bulk-like 3Y-TZP grains of 4 μm in depth in which monoclinic laths were observed. Regarding residual compressive stresses, they can extend below the surface until a depth of approximately 5 μm , decreasing progressively and reaching a maximum of 700 MPa. Compressive stresses can improve the strength (e.g., from 1200 to 1300 MPa in biaxial bending) as reported by Muñoz-Tabares *et al.* (2011) and have a positive effect in the so-called hydrothermal degradation process. For example, ground 3Y-TZP can be safe from hydrothermal degradation (131°C-96 h in autoclave) due to the formation of a tetragonal refined-top layer, as proposed by Muñoz-Tabares and Anglada (2012).

Fig. 4 Crack rate versus stress intensity factor of biomedical grade alumina and zirconia ceramics.

However, it is necessary to keep in mind that heavily ground samples may also display degraded mechanical behavior and poor aging resistance, both resulting from a complex balance between residual stress field and surface microcracking.

The use of 3Y-TZP for developing biomedical devices is explained by the fact that, compared to alumina, 3Y-TZP ceramics exhibit higher resistance to slow crack growth and higher strengths (especially if machined because the apparent toughness can reach $20 \text{ MPa}\sqrt{\text{m}}$). Hence, the ultimate compressive load of 3Y-TZP femoral ball heads can be 2–2.5 times higher than that of alumina ball heads of the same diameter and neck length (Piconi and Maccauro, 1999). So, if the use of 3Y-TZP stopped in orthopedics early 2000s, is without any doubt because of its sensitivity to aging. Paradoxically, the main advantage of zirconia, i.e., its phase transformation capacity, can also be its main drawback when t-m transformation takes place at the surface in an uncontrolled manner. It is also important to understand at this stage that giving a monoclinic content at the surface as an indicator of “damage” is not correct as t-m associated to grinding and surface treatments may be positive while negative if associated to water-assisted aging. The decrease (or increase) of mechanical properties related to t-m transformation is thus a balance between the beneficial compressive stresses and the negative microcracking effect.

Aging Process and its Consequence on Zirconia-Based Biomedical Implants

Giving a comprehensive review of the aging mechanism would again considerably extend the scope of this chapter. The readers not familiar with this field can refer to the excellent review of Lawson (1995) or a more recent overview (Chevalier, 2006). The excitement created by Y-TZP materials in the 1980s was already dampened by the phenomenon of aging (Kobayashi *et al.*, 1981). The authors revealed that Y-TZP ceramics could suffer a slow, t-m phase transformation at the surface in contact with humid atmosphere, followed by microcracking and a loss in strength. Following this work, a series of works were published with an attempt to understand the basic micromechanisms behind the t-m transformation and to reduce this detrimental phenomenon. The main features of this so-called “Low Temperature Degradation” (LTD) are the following:

- (1) Transformation proceeds most rapidly at temperatures of $200\text{--}300^\circ\text{C}$ and is time dependent;
- (2) Water or water vapor enhances the transformation;
- (3) Transformation proceeds from the surface to the bulk of zirconia materials;
- (4) Higher stabilizing content or finer grain size increase the resistance to transformation;
- (5) Processing conditions affect the aging behavior;
- (6) Surface post-treatments such grinding and polishing can modify the resistance to aging.

Several models proposed mechanisms by which the presence of water could promote t-m transformation. Sato and Shimada (1985) have proposed a chemisorption of water to form Zr-OH at the surface of zirconia, which results in the accumulation of strain energy able to trigger the t-m transformation. Yoshimura *et al.* (1987) further refined this model proposing the chemisorption of water as the key mechanism for having aging but attributing the accumulation of stresses to the migration of OH species at the surface and into the zirconia lattice. The diffusion of OH is promoted by the presence of oxygen vacancies in the lattice of yttria (yttria and zirconia being tri- and tetravalent cations, respectively). This could explain the different LTD behavior of Y-TZP versus Ce-TZP ceramics (cerium being tetravalent, only fewer oxygen vacancies are present, which gives rise to a much better aging resistance). Other models postulated a reaction between H_2O and yttria (Y_2O_3) to form Y(OH)_3 compound, leading to a

Fig. 5 Model for the increase in internal stresses due to water chemisorption and diffusion of OH^- in the lattice. Adapted from Yoshimura, M., Noma, T., Kawabata, K., Somiya, S., 1987. Role of water on the degradation process of Y-TZP. *Journal of Materials Science Letters* 6, 465–467.

depletion of the stabilizer content and consequently to t-m transformation. However, today, the depletion of Y_2O_3 during LTD is considered unlikely and the fundamental role of internal stresses model of Yoshimura is the most accurate in its description of the different features of LTD. This model is schematically represented in Fig. 5.

When the stresses due to the diffusion of OH^- species reach a critical level in the lattice, then a grain or a part of it can undergo phase transformation. Transformation starts first in isolated grains located on the surface in contact with water, body fluids or water vapor (e.g., under autoclave conditions). The initial transformation of specific tetragonal grains (nucleation sites) can be related to their metastability degree (either to a larger grain size and/or lower yttria content), their orientation from the surface, the presence of residual stresses or even of the cubic phase, often neglected in most of the experimental works despite its critical influence (Chevalier *et al.*, 2004). As shown in Fig. 6, the nucleation of the transformation leads then to a cascade of events occurring neighbor to neighbor. The transformation of one grain leads to a volume increase thus stressing up the neighboring grains and results in microcracking. This offers a path for the water to penetrate deeper into the specimen, triggering new nucleation and growth sites for t-m.

The transformation occurs, therefore, by a nucleation and growth process, often described by Mehl–Avrami–Johnson laws (Chevalier *et al.*, 1999b). The growth stage depends on several microstructural features such as porosity, residual stresses, grain size, etc. Several studies have been performed to investigate the aging kinetics of 3Y-TZP ceramics at ambient temperature and under accelerated conditions (in autoclave, e.g., at $134^\circ C$, 2 bars). However, if all show some amounts of t-m phase transformation, the kinetics data are strongly scattered due to differences in the processing (dispersing, shaping, sintering) affecting the grain size, composition, residual stresses and density and in the post-processing steps (cutting, grinding, polishing, chemical etching, sandblasting, etc.). This fact led to misunderstanding and some zirconia producers stated that products manufactured with biomedical 3Y-TZP were safe, while competitors and scientific works declared at the same time the contrary. Again, some works showed excellent behavior of 3Y-TZP femoral heads after several years in-vivo, while others showed enhanced roughening associated with severe wear and osteolysis around the implant, as consequence of aging. This is once more due to differences in the processing from one supplier to another. During the short history of 3Y-TZP in orthopedics, many varieties have come into existence -black/white zirconia, HIPed heads, non-HIPed heads- and all showed different LTD resistance. The consequences of aging process on the long-term performance of zirconia implants can be: (1) the roughening of the surface that leads to increased wear and (2) microcracking that leads to grain pull-out, the generation of particle debris and, possibly, premature failure when microcracked, damaged zones reach the critical size for slow crack growth to proceed.

At this stage of the chapter, it is important to recall the main facts related to the failures of some Prozyr® femoral heads already implanted. By mid-1998, Saint Gobain Demarquest (SGD) had made thousands of femoral balls with very low failure rates. However, in 2001 catastrophic head fracture were reported (Clarke *et al.*, 2003; Maccauro *et al.*, 2004) linked to a Prozyr® batch in which fracture rates as high as 42% occurred 21–46 months after surgery. At that time, it was said by the manufacturer that failure occurred via “unexpected” and accelerated aging process observed in only some batches of Prozyr® femoral heads. It is clear today that these failures were caused by an “unusual” accelerated aging of the cone region of the heads due to a change carried-out in the sintering step by SGD. In fact, in 1998, a change from a batch to a continuous flow tunnel furnace produced slightly modifications of microstructure and density, leading to a decrease in aging resistance. These relatively small changes in density were undetectable by the quality control but thorough analysis showed that the inner core of the ball was not as dense as usual and could contain percolating porosity; the change in the manufacturing process was the reason for the sudden increase of Prozyr® failure rates. This critical situation led to SGD to pull 3Y-TZP femoral heads off the market. In 2001, considering that small changes

Fig. 6 Schematic aging representation showing the nucleation of t-m in a grain at the surface, the t-m transformation propagation from neighbor to neighbor, accompanied with surface uplift and microcracking. Transformed grains are gray and penetration of water paths in red. From Chevalier, J., 2006. What future for zirconia as a biomaterial?. In: Leong, K. (Ed.), *Biomaterials*, vol. 27. Elsevier, pp. 535–543.

in the processing could induce similar dramatic events in other 3Y-TZP implants, European and American regulatory agencies recalled thousands of 3Y-TZP femoral balls. By 2002, all Prozyr® sales stopped and SGD retired from the medical field.

The crisis of 2001 emphasized the importance of accurate process control for such metastable zirconia implants, but should not lead to any conclusion about the behavior of a zirconia in the body. Maybe more critical are the reports that showed surface degradation of zirconia implants, or strong osteolysis. Haraguchi *et al.* (2001) reported for the first time, two cases of a surface degradation (roughening and microcracking) caused by t-m phase transformation. The zirconia used in this work, presumably processed by Kyocera, satisfied the requirement later specify in standards, that is, maximum amount of monoclinic phase after accelerated aging in autoclave at 134°C under a pressure of 0,2 MPa for a period of 5 h < 25% (International Organization for Standardization, 2016a). However, the authors measured monoclinic contents of 20% and 30% in both heads after a short period of 3 or 6 years of implantation, respectively. They also reported a strong increase in roughness, growing from 6 nm to 120 nm. Another paper from Catledge *et al.* (2003) confirmed the degradation of surface properties for some explanted zirconia heads that had undergone various degrees of phase transformation, ranging from 0% to ~78% monoclinic content after 62 months in service. The hardness dropped from 18 GPa to 11 GPa for high transformation fractions, which indicates extensive microcracking in the transformed regions. Contrasting with these poor clinical experiences, other authors also reported a better behavior of zirconia femora heads, at least at middle-term follow-up (Caton *et al.*, 2004). For instance, 22 mm diameter zirconia heads implanted for 45 months showed less than 10% monoclinic content, with apparently neither increase in roughness or grain pull-out. These different clinical experiences and events have shown that LTD was relevant in-vivo and may lead to failure of implants after a short duration. They also have confirmed the strong variability of zirconia femoral heads with regard to aging resistance. As discussed earlier, main parameters affecting LTD are the density (open porosity offers

water molecules easy access to the bulk), grain size (finer grain size increase the stability of zirconia, so the resistance to t-m transformation), the homogeneity of microstructure/phase distribution (negative effect of residual cubic phase) and the residual stresses (positive effect if tensile on the surface).

Fortunately, it is now possible to assess the sensitivity against aging of biomedical grade zirconia prior to be implanted. Due to the thermally activated character of the t-m transformation, accelerated aging tests in autoclave were standardized. It is proposed for example that autoclaving 1 h at 134°C under vapor steam (0.2 MPa) has roughly the same effect as few years in-vivo. Nevertheless, it must be known that depending on the apparent activation energy used for extrapolating LTD kinetics, the results may vary and that such accelerated aging tests do not take into account possible coupling effects on the aging kinetics. For example, increased aging kinetics in 3Y-TZP femoral heads has been observed when accelerating aging tests were coupled with wear tests (Douillard *et al.*, 2012; Gremillard *et al.*, 2013). There is still a great need of more advanced studies on zirconia aging, with particular interest in finding the correlation between compositional and microstructural features, post-treatment procedures, wear, cyclic loading, shocks and LTD resistance by developing new accelerated tests in-vitro and in-vivo. Recently, Wei and Gremillard (2018) proposed a new protocol to predict the aging behavior of 3Y-TZP from microstructural parameters (grain size, yttria partitioning and monoclinic, tetragonal and cubic amounts) able to allow adapting the sintering conditions in order to maximize the LTD resistance. However, it is not yet known whether shear, tensile or compressive stresses could induce/hinder aging, thus affecting its kinetics.

Currently, the main features of zirconia LTD are well known and there are different tools and standards to assess the aging resistance of a given Y-TZP before its use as a medical implant material. Moreover, 3Y-TZP aging-resistant compositions containing small amounts of alumina (i.e., 0.25 wt%) or partially to fully-stabilized zirconia with higher yttria content have been first developed at the laboratory scale (Zhang *et al.*, 2014) but are now available commercially (e.g., Tosoh TZ-3Y-E with 0.1–0.4 wt% Al_2O_3 , TZ-8Y with 8 mol% Y_2O_3). The improved 3Y-TZP LTD resistance when adding small quantities of alumina is linked to the segregation of Al^{3+} at the grain boundaries and the heterogeneous distribution of Y^{3+} . In Y-rich systems, the improved aging resistance is due to the full stabilization of the cubic phase, as in 8Y-FSZ ceramics (FSZ for *Fully Stabilized Zirconia*). The better understanding of LTD phenomenon and microstructural features effect has allowed yttria-stabilized zirconia to take off in the dental field, first as crowns, then as implants (Ren *et al.*, 2011; Li *et al.*, 2019b) as shown in Fig. 7.

To date there is no alarming report on the resistance to aging of yttria-stabilized zirconia used in dentistry, except in a few pre-clinical trials and research works involving special implants in which a new surface design or new surface treatments have been applied (Sanon *et al.*, 2015).

Optical Properties of Yttria-Stabilized Zirconia

Although 3Y-TZP zirconia is the strongest ceramic oxide in terms of flexural strength (typically > 1 GPa) and resistance to fracture (toughness of 5–8 $\text{MPa}\sqrt{\text{m}}$), other ceramics in the $\text{ZrO}_2\text{-Y}_2\text{O}_3$ system containing up to 8 mol% of yttria have emerged driven by dental restorative applications. Their optimized esthetic properties and the advances made in CAD/CAM technologies allow the realization of dental crowns and frameworks based on several Y-stabilized zirconia, which can be also colored to match the patient teeth's coloring. Depending on the content of yttria, these new ceramics can be opaque, "highly-translucent" or "ultra-translucent" and characterized by different structural features but also lower strength as compared to 3Y-TZP. However, they exhibit a better resistance to aging as predicted by the phase diagram of Fig. 1, since the higher the stabilizer amount, the higher the "stable" cubic phase content.

Fig. 7 Illustrations of full-ceramic crowns, fixed-partial denture or bridges and implants made of 3Y-TZP by (a) CAD/CAM and (c, d) stereolithography 3D printing; the corresponding change of size of implant after printing, debinding and sintering is shown. Fig. 8 Effect of intrinsic and extrinsic factors on optical properties of Y-TZP dental zirconia. From Shahmiri, R., Christopher, O., Hart, J., Sorrell, C.C., 2018. Optical properties of zirconia ceramics for esthetic dental restorations: A systematic review. *Journal of Prosthetic Dentistry* 119, 36–46.

As shown in Fig. 8, the color and appearance of monolithic Y-TZP zirconia dental restorations depend on intrinsic and extrinsic characteristics. Color matching and improved translucency is achieved by adding small amounts of dopants such as Fe₂O₃, Pr₂O₃, Al₂O₃, LaAl₂O₃ etc.

There are several other parameters, which may be varied to improve the esthetic; the interested reader may refer to the review papers proposed by Shahmiri *et al.* (2018) and Kontonasaki *et al.* (2020). Zirconia materials developed for dental applications typically contain 2–3 mol% of yttria (<15% cubic phase), 4–5 mol% of yttria (>50% cubic phase) or 6–8 mol% of yttria (up to 100% of cubic phase). The grain sizes range from 200 nm to 1500 nm. For 3Y-TZP, the refractive index is low (2.214) but that of birefringence is high (0.038), leading to greater scattering that can alter the color and increase the opacity. On the other hand, fully-stabilized-zirconia materials (FSZ with 100% of cubic phase) exhibit lower refractive index (e.g., 2.177 for 9 mol% of yttria) and no birefringence, which markedly improve translucency. However, in Y-rich ceramics the strength and toughness diminish because cubic zirconia does not undergo stress-induced transformation. Therefore, a compromise must be found in order to adapt the stabilizer content to the required properties, so the mechanical resistance versus esthetic depending on the application (e.g., restoration of the posterior or frontal regions of the mouth). In general, opaque zirconia (e.g., compositions close to 3Y-TZP) offers significantly greater strength (800–1000 MPa) and is indicated for the posterior regions of the mouth, while ultra-translucent zirconia (e.g., 5Y-PSZ) has lower mechanical properties (typically 500 MPa) but more natural esthetic appearance (required in the front part of the mouth). Even so, the strength of 5Y-PSZ (e.g., 500 and 900 MPa for Zpex Smile/Tosoh and Lava Esthetic/3M ESPE, respectively) is still higher than that observed in lithium disilicate (LS2) glass-ceramics (400–500 MPa for IPS e.max/Ivoclar Vivadent) (Zhang and Lawn, 2018).

Efforts are underway to further improving the esthetic and the mechanical properties of Y-TZP zirconia, for example, by incorporating small quantities of other oxides. Fig. 9 shows the effect of dopants (Al₂O₃, La₂O₃) on the mechanical, LTD and optical properties of 3Y and 5Y systems as reported by Zhang *et al.* (2015, 2016). The incorporation of alumina (0.05–0.25 wt% Al₂O₃) and/or 0.2 mol% La₂O₃ certainly enhances 3Y-TZP translucency and aging resistance but can also decrease mechanical properties. Co-doping 3Y-TZP with small amounts of alumina and lanthania leads to the segregation of Al³⁺ and La³⁺ at the zirconia grain boundaries. Segregation seems to be a key factor to design hydrothermally stable and high-translucent Y-TZP ceramics, while maintaining excellent mechanical properties.

Final Discussion: The Past, the Present and the Future of Y-TZP Zirconia in the Biomedical Field

The problem caused by selected batches of Prozyr® femoral heads in 2001 and the wide variability of research/clinical results regarding 3Y-TZP aging behavior highlighted the lack of precise specifications to ensure excellent long-term behavior of biomedical zirconia at that time. Since then, the mechanisms behind LTD and the effects of coupling different solicitations (biological,

Fig. 9 Microstructure, Weibull plot for 4-point bending, Monoclinic phase transformed during accelerated aging tests and translucency parameters of highly translucent Y-TZP ceramics containing 3(3Y) and 5(5Y) mol% of Y_2O_3 , with 0.25, 0.1 or 0.05 wt% of Al_2O_3 (referred to as 0.25Al, 0.1Al and 0.05Al) or 0.2 mol% of La_2O_3 (referred as 0.2 La). Adapted from Zhang, F., Vanmeensel, K., Batuk, M., *et al.*, 2015. Highly-translucent, strong and aging-resistant 3Y-TZP ceramics for dental restoration by grain boundary segregation. *Acta Biomaterialia* 16, 215–222. mechanical, wear, etc.) and microstructural/compositional features have been studied in depth. Today, we can better predict the aging of zirconia end products thanks to existing standardized procedures (proposed by ISO and ASTM standards since 2008) and other more complex tests that are currently being developed on a laboratory scale. These standards have been inspired in research works which have shown for instance that one hour of autoclave treatment at 134 °C had theoretically the same effect as few years in vivo, allowing to assess the aging sensitivity of a given zirconia in shorter times (Chevalier *et al.*, 1999b). However, even if enormous progress has been made on this aspect, recommendations of current standards (International Organization for Standardization, 2015a) need still to be revised (e.g., less than 25% of t-m transformation after 5 h of accelerated aging at 134 °C and 0.2 MPa). For instance, according to the standard for dental ceramics (International Organization for Standardization, 2015b) recommendations are made for samples having followed a specific surface preparation (i.e., grinded to 30–40 μm and then polished to 15–20 μm) which gives surface finishing/residual stresses very different from those observed in final dental products on in other biomedical devices. Standards have already been revised in the past following advances in the research field. For example, the first guidelines fixed the maximum grain size in biomedical-grade 3Y-TZP to a linear intersection distance of 0.6 μm but as numerous studies clearly showed a dramatic decrease of aging resistance above a linear intersect of 0.4 μm, the standard limit was modified accordingly. In current versions of standards, X-ray diffraction (XRD) allows to quantify the t-m transformation. However, in our opinion this technique is not enough alone and should be coupled to other ones for better characterizing the transformation, for example optical interferometry, atomic force microscopy and scanning electron microscopy of aged cross-sections (Chevalier *et al.*, 1999b; Deville *et al.*, 2004).

3Y-TZP started to be used in the dental field right after being “banished” from orthopedics, in which alumina-based composites containing zirconia become the standard. As in the case of orthopedics, zirconia ceramics were introduced as an alternative to alumina, first for manufacturing crowns, frameworks and abutments and then dental implants. The aging of 3Y-TZP dental materials could be an issue if lessons learned from the past are not taken into account. Let us recall here that it was the issue of break in series of Prozyr® femoral heads in 2001 that highlighted the coupled phenomena (aging, microstructure, slow-crack growth), contributing in this manner to their knowledge. If we had the knowledge of today on this subject 20 years ago, prostheses and femoral heads in zirconia would be currently among the safest on the market! By paying attention to the processing and post-treatments of dental materials and their impacts (which are now relatively well known), one can therefore guard against reckless risks.

Particular attention must be paid to dental implants where the roughness of their surface must be increased to improve osseointegration. Some studies start to report premature failure of zirconia dental implants (Scherer *et al.*, 2019) and restorations (Oilo and Arola, 2018) that have mainly been related to surface defects (where stress concentrations would be induced) or to design issues (due to the erroneous tendency to copy what is done on titanium implants). On the basis of available results, adapted protocols and quality controls have to be implemented to guarantee very precisely the main characteristics of dental zirconia (density, composition, grain size, grinding and polishing states, surface flaws and modifications, implant/restoration design, shape of threads, etc.), thus minimizing the risk of failure.

There is a room for further technical progress of currently available dental Y-TZP ceramics. For implants, the use of 3Y-TZP is preconized in order to be able to withstand the complex and high stresses to which they are subjected. Two-pieces dental implant

systems seem to be more desirable for technical reasons, although more challenging because of limitations related to connections. For external restorations, the zirconia-yttria composition can be adapted to the location in the mouth always taking into account the trade-off between esthetic and mechanical properties. Other dopants can also be added in order to improve the optical properties (i.e., transparency and color to match the aspect of the remaining natural teeth). Further innovation in additive manufacturing (AM) technologies could enable novel designs and solutions that are presently too high-cost. Digital dentistry is one of the fastest growing areas of AM technology and possible applications include the fabrication of crowns, bridges, dentures, models, surgical guides, implants and other orthodontic materials. Recently, some works have reported the use of ceramic stereolithography in manufacturing 3Y-TZP bridges, crowns, teeth and implants (Li *et al.* 2019a,b; Lian *et al.*, 2019). Nevertheless, important challenges as the reliability of the process, surface finishing, processing-defects and ceramic debinding/densification procedures must be overcome in order to implement an AM productive solution. Novel ultra-translucent and colored monolithic Y-TZP zirconia ceramics present considerably improved esthetic and translucency, better aging resistance but lower strength. They have to be further evaluated both *in vitro* and *in vivo* for their long-term potential behavior.

Taking advantage of its superior mechanical properties, novel Y-TZP biomedical applications are also being developed in the field of neuro-stimulation and heart's implantation, as biocompatible containers of electronic modules. Thin (40 μm), very flexible and near IR-transparent foils are used for housing ultra-thin implantable neuro-stimulators which contain an infrared photovoltaic module able to recharge the device without external wiring (Chevalier and Gremillard, 2017). Once again, an absolute vigilance must be paid to the LTD phenomenon, due to the very thin thicknesses of the parts implemented here and, above all, to the degree of criticality of these types of applications (Le Coadou *et al.*, 2015).

Conclusion

Zirconia and especially 3Y-TZP is the toughest ceramic oxide first used in orthopedics and then in the dental field due to its major advantages in terms of reliability versus crack propagation and delayed failure and consequently in terms of freedom to design. Even if the LTD remains a point of vigilance, zirconia 3Y-TZP will always keep a place of choice in the biomaterial field, thanks to its mechanical properties not yet equaled by another ceramic and to its very fine microstructure, which allows developing special optical properties.

If we look at the past, the failure episodes of Prozyr® femoral heads in 2001 which banned the use of 3Y-TZP in orthopedics have also opened a controversial debate about the future of zirconia as a biomaterial, which has helped deepen understanding of LTD. The unpleasant incidents, even if dramatic in some aspects, have led the scientific and orthopedic community to study the behavior of zirconia, especially with respect to aging *in vitro* and *in vivo*. Current knowledge shows that the strong variability of the degradation of zirconia *in vitro* and *in vivo* is related to the strong influence of processing and post-treatment procedures on aging kinetics. Early failure rates in some dental devices as reported in the past show that the 3Y-TZP sensitivity to undergo t-m transformation and its brittleness as a ceramic (even if tougher than alumina or glass-ceramics) remain the most critical factors in the dental field. It may seem that dental implant failures are less critical than failures in orthopedics, but it must be remembered here that the surgical procedure for retrieving a broken dental implant often involves a bone graft, additional healing times, discomfort for the patient and extra-costs, but more importantly, that all these health problems are now preventable.

Even if we know today how to avoid LTD and its consequences, new clinical studies and coupling test procedures are necessary in order to better identify the set of relevant technical and biological factors, which would seriously affect the durability of Y-TZP bioceramics. Certainly, 3Y-TZP ceramics and novel rich-yttria compositions can be excellent materials of choice in the area of dental restoration if all the variables linked to the processing and post-processing of the material are perfectly mastered. At the present as in the past, the future of zirconia as biomaterial will depend on the ability to control materials characteristics (which can be supplier-dependent) and applied post-treatments (sintering, polishing, grinding, etc.). For example, the hydrothermal stability limits for using zirconia as a biomaterial are standardized, but standard's guidelines do not include the effect of surface preparation on the aging resistance (International Organization for Standardization, 2016a). In other words, existing standards are useful for investigating the "intrinsic" sensitivity to aging of a given zirconia, but it may not give relevant information on the aging kinetics of "real" dental devices. Efforts must be made to develop new tests and normative procedures capable of taking into account surface modifications applied to the real products or devices and the coupled effect of the environment and the mechanical, chemical and biological stresses. We can certainly be more positive today about the future of Y-TZP as biomaterial compared to our position a decade ago. Although LTD remains to be monitored with precision, today we have all the knowledge to avoid it in the range of temperature and time compatible with most applications. Thus, thanks to its exceptional mechanical properties, the ease of implementation of CAD-CAM technologies and the tunability of optical properties, the future of the zirconia stabilized with yttria in the biomedical field, especially in the dental field, still looks very promising!

Introduction

Total hip replacement (THR) surgery during which a worn natural hip joint is removed and replaced by a prosthesis was introduced by Dr. Charnley in 1960 (Campbell and Rothman, 1971) and has become a standard procedure with approximately 500,000 cases every year and an annual growth rate of a few percent (Rahaman *et al.*, 2007). Total knee replacement (TKR) is quickly catching up due to higher annual growth rates. The human hip is an enarthrosis (ball and socket joint). Indications are either cases of arthrosis or – less frequently – fracture, e.g., due to severe accidents (Crawford and Murray, 1997).

The natural enarthrosis is removed and replaced by a synthetic pairing (the prosthesis). The joint region of the femur is cut off and a metal stem (typically a titanium alloy) is inserted in the femur (by cementation or press-fit). The joint region in the pelvic bone is also machined away and a metal cup is implanted. The metal stem and cup are often surface structured and coated in order to promote safe long term fixation in the surrounding bone (Rahaman *et al.*, 2007).

The joint as such is represented by a ball fixed on a conical taper on the stem and a socket insert in the metal cup. The classical solution is metal balls of, e.g., cobalt chromium alloy and polymer counterparts of very stable ultrahigh molecular weight polyethylene (UHMWPE) (Geerdink *et al.*, 2006). Highly crosslinked polymers offer higher wear resistance but suffer from inherent brittleness (Bradford *et al.*, 2004). The lifetime of these standard prostheses is limited by wear of the metal/polymer pairings, which can either destroy the polymer or cause aseptic loosening of the joint by release of wear debris. Other negative effects are corrosion of the metal and release of metal ions. The lifetime strongly depends on the weight and mobility of the patient and may be individually very different; the estimated average lifetime of such a joint is in the range between 10 and 20 years (Crawford and Murray, 1997). It is reported that ~25% of implants fail prematurely (Emery *et al.*, 1997). Morell carried out an in detail analysis of a fractured alumina ball head (Morell *et al.*, 2012).

The motivation for introducing ceramics to THR was therefore mainly the reduction of wear in the artificial joint and thereby to avoid the risks and cost of revision surgery (Lavernia *et al.*, 1995). The extremely hard ceramics do not wear themselves, are well wetted by the synovial fluid and – if properly machined – also cause much less wear in the polymer counterpart (Willmann, 1996).

Biomedical grade alumina was the first material used in THR since the 1970s (Boutin *et al.*, 1988). Alumina while being hard and abrasion resistant is also relatively brittle ($K_{IC} \sim 3\text{--}4 \text{ MPa}\sqrt{\text{m}}$). Over the last 20 years, the continuous improvement of material and manufacturing processes has led to a reduction of the failure rate of the alumina balls by reducing the number and size of defects (Willmann, 1996).

Yttria stabilized tetragonal zirconia polycrystals (Y-TZP) was introduced in the 1990s to overcome the brittleness of alumina (Christel, 1989). Y-TZP is much stronger and tougher than alumina. However Y-TZP being a non-equilibrium compound suffers from low temperature degradation (LTD). This was discovered first by Kobayashi *et al.* (1980) for higher temperatures. It was however not considered relevant for materials operating at low temperature in the living environment. In the 1990s, the failure of a large number of components in vivo and the subsequent revision surgeries and claims for damage together with an FDA (Food and Drug Administration) recall of zirconia femoral heads in 2001 led to an early end of the promising developments in Y-TZP prostheses (Chevalier *et al.*, 2007). As a matter of fact the new generation of ageing resistant Y-TZP materials was already under development and close to market introduction at this time (Burger *et al.*, 1997).

The need for a tougher and stronger material with high LTD resistance initiated the development of zirconia toughened alumina (ZTA) materials. The performance of Y-TZP and ZTA materials exposed to ageing and wear has been investigated in detail (Gremillard *et al.*, 2013). Today the world's top-selling ceramics (BioloX Delta® by CeramTec, Germany) for hip prostheses is a zirconia toughened composite (ZTC) which besides zirconia alumina and yttria contains small amounts of chromium and strontium oxides (Kuntz, 2006). The basic recipe had originally been developed for cutting tool applications under the abbreviation DC25 (25 mass % which correspond to 18 vol% zirconia) but was then found to be an excellent material for THR (Burger and Richter, 2001). As the patent had expired a few years ago, other manufacturers started manufacturing materials of similar composition. A summary on recent developments in biomedical grade ZTA is given by Kurtz *et al.* (2014).

An important point which deserves to be mentioned in this review is the regulatory environment imposed by government organizations such as the FDA in the USA or the corresponding organizations in other countries. They were regulatory procedures introduced to protect the patients and ensure a constant and reliable quality of medical products. For this purpose, all manufacturing procedures of a medical product brought successfully to the market and certified by these agencies are fixed. Any later changes of materials procedures etc., are subject to a re-assessment. As such re-assessments are costly and time consuming, products are seldom changed unless a serious reason is given (e.g., superior competitor product or, fundamental improvements in materials technology) which justifies the effort. The industry is therefore rather conservative. The same measures taken to protect the patients are somewhat conflicting towards innovations in the field.

ZTA – The Basics on the Materials

ZTA is a composite ceramic containing a zirconia dispersion in an alumina matrix. This combination boosts mechanical and tribological properties compared to alumina ([Wang and Stevens, 1989](#)). Depending on the amount of zirconia particles, their size, dispersion quality, zirconia stabilizer content (if any) and stabilizer type as well as firing conditions, a very wide broad range of properties can be realized in ZTA materials. In this context, it is beneficial to understand the role of the zirconia dispersion and the basic reinforcement concepts applied in ZTA. The reinforcement mechanisms in pure ZTA are transformation toughening, microcracking, and residual stress due to thermal mismatch of the phases and the fraction of transformed (monoclinic) zirconia.

Tailoring of the Microstructure

The effects of zirconia addition on the microstructure of ZTA materials were studied in detail by [Lange \(1982\)](#). They found out that zirconia is an efficient grain growth inhibitor for the alumina matrix. However, zirconia grains must be so numerous as to block all 4-junctions and thereby prevent coalescence of alumina grains. The threshold defined by [Lange and Hirlinger \(1984\)](#) is at ~ 7 vol% zirconia. It should however be considered that the effect will depend on the starting grain size of the alumina and zirconia and the quality of mixing of the two phases. The finer the zirconia phase and the better its dispersion degree the more stable will the microstructure be towards overfiring.

Figs. 1–4 show ZTA materials with zirconia fractions of 5–24 vol% ([Kern, 2010, 2012a, 2013; Kern et al., 2016](#)). All materials are based on the same 300 nm α -alumina by addition of nanoscale zirconia by mixing and milling and subsequent hot pressing (unpublished images, authors own work). It becomes clear that in AZ5 not all 4 junctions can be blocked and that in addition to

Fig. 3 Microstructure of alumina – 17 vol% zirconia (AZ17) made by mixing and milling.

Fig. 4 Microstructure of alumina – 24 vol% zirconia (AZ24) made by mixing and milling.

zirconia grains at the grain boundaries some zirconia grains were trapped inside alumina particles due to grain growth of the matrix. In AZ10, these intragranular zirconia grains become rare and completely disappear at higher zirconia contents. In AZ17 (a typical biomedical grade composition) and even more pronounced in AZ24 (already out of biomedical grade specification), aggregation of zirconia grains is clearly visible.

Obtaining a perfect dispersion is therefore a matter of powder choice and proper choice of processing parameters. The problem was identified quite early and theoretically described by [Garvie \(1985\)](#) and [Garvie and Swain \(1985\)](#). The zirconia dispersion may be divided in three fractions. The first consist of oversize grains which transform to monoclinic during cooling from sintering temperature and are no longer available for transformation toughening. However, they may provide some toughness by inducing microcracking of the ceramic. The second fraction refers to undersized grains with a diameter lower than a critical size D_C^I which do not transform at all even if exposed to stress. What remains as an exploitable size fraction for transformation toughening are grains ranging from diameters D_C^I (lower limit) to the critical grain size D_C . The exploitable size range is surprisingly small. [Garvie \(1985\)](#) and [Garvie and Swain \(1985\)](#) calculated values between 380 and 460 nm. [Naglieri et al. \(2013a\)](#) showed that the range depends on the zirconia content and may range from 435 to 485 nm for alumina – 5 vol% unstabilized zirconia to 465–565 nm for alumina – 10 vol% unstabilized zirconia. In case of stabilized zirconia such values will be shifted towards larger grain sizes.

Distribution of zirconia and prevalence of isolated grains is also important for the aging (LTD) characteristics of zirconia materials. Transformed grains can trigger the transformation of adjacent grains (no matter if stress – or LTD-induced) ([Chevalier, 2006](#)). ZTA compositions below the percolation threshold in which the zirconia grains are not in contact (for grains of equal size $\sim 16\%$ zirconia content) are therefore considered LTD stable while such with higher contents will be prone to degrade. This consideration has led to the restriction of the maximum zirconia fraction in biomedical grade ZTA to <30 mass% ~ 22 vol%.

Materials made by mixing and milling react very sensitively to changes in dispersion conditions ([Heijman et al., 2002](#)). The initial approach to solve this problem was to make alumina–zirconia powders by sol–gel method which is feasible but extremely

Fig. 5 Microstructure of alumina – 10 vol% zirconia (AZ10) made by powder coating.

Fig. 6 Grain size of alumina and zirconia grains in AZ10 materials produced by mixing and milling vs. powder coating depending on sintering temperature.

uneconomical compared to a mixing and milling approach (Messing and Kumagai, 1989; Srdić and Radonjić, 1997). Later, it was proposed to crystallize zirconia particles on the surface of commercially available alumina powders by a wet chemical method (named surface coating process) (Palmero *et al.*, 2014).

The efficiency of this latter approach to obtain zirconia dispersions with a narrower zirconia grain size distribution was successfully demonstrated in various studies. Materials showed enhanced toughness and resistance to subcritical crack growth due to the higher transformable zirconia fraction and the LTD resistance was also enhanced (Deville *et al.*, 2003; Palermo *et al.*, 2009; Naglieri *et al.*, 2013a; De Aza *et al.*, 2003). Fig. 5 shows the microstructure of a AZ10 material made from a zirconia coated alumina powder sintered at 1525°C/3 h in air (Authors own work, related to: Kern *et al.*, 2015). Fig. 6 shows the grain sizes of alumina and zirconia in AZ10 ceramics made by mixing and milling and by surface coating process (Kern *et al.*, 2015; Kern, 2016). Evidently the alumina matrix and the zirconia dispersion are much finer in case of the “coated” starting powder. However, it is also seen that the zirconia grain size is in both cases at the lower end of the optimum range. This would also explain the moderate toughness of both materials (3.8–4.7 MPa√m for the coated, 4–5 MPa√m for the mixed ZTA). To the authors’ knowledge the concept was never technically implemented. The main causes were most probably regulatory ones, i.e., the need for a complete re-assessment of the production cycles and concerns about the up-scalability of the concept from lab to production size. The heat treatment of the coated powders is a tricky procedure to ensure a homogeneous crystallization of the zirconia nanoparticles on the alumina powder (Naglieri *et al.*, 2010). Another important point to be considered is the progress in conventional mixing and milling processes which today are capable to produce ZTA qualities far superior to the reference materials presented in the studies. Dispersion quality also affects the efficiency of reinforcement mechanisms as shown in the following paragraph.

Reinforcement Mechanisms

Typically, there are three basic reinforcement mechanisms in ZTA materials.

Residual stress fields result from different thermal expansion coefficients and elastic properties of alumina and zirconia phases. Besides these “regular” residual stresses, there is an additional stress increment exerted by zirconia grains which have transformed from tetragonal to monoclinic during cooling from high-temperature sintering (Gregori *et al.*, 1999).

Residual stress can be relieved and additional fracture surface can be created by microcracking. The effects may happen prior to loading (existing microcracks) or occur during loading by a superposition of residual and working stress. Residual stress – tensile or compressive – may initiate or impede microcracking.

Finally, there is transformation toughness, where transformation of tetragonal zirconia grains can be triggered by applied stress. This results in a martensitic tetragonal to monoclinic transformation associated with volume expansion of 4%–5% and shear. In contrast to Y-TZP, which transforms predominantly dilating, the transformation of isolated zirconia particles in ZTA may exploit both dilatation and shear and result in high transformation efficiency.

Microcracking

The first ZTA materials that were introduced by Claussen, exclusively exploited the concept of microcracking (Claussen, 1976). The materials contained a large fraction of large unstabilized zirconia particles which transformed to tetragonal during sintering and re-transformed to monoclinic during cooling down. As the $t \rightarrow m$ transformation of zirconia is associated with volume expansion and shear, the expanding zirconia particles exert tensile tangential stresses in the surrounding matrix. These stresses scale with r^3 (r = particle size) and may lead to circumferential microcracks (Evans and Faber, 1981). When a proceeding crack interacts with these microcracks, the fracture energy is dissipated by creating higher fracture surface which leads to an enhanced fracture resistance. While the toughness increase can be quite significant, these “pre-existing microcracks” – depending on the microstructure – may lead to a damaged microstructure and a loss of strength (Claussen, 1976). Microcracks may moreover create voids into which synovial fluid may penetrate and induce subcritical crack growth (Chevalier, 2006). Therefore, this toughening mechanism in its pure form is not suitable for biomedical grade ZTA.

Transformation toughening

In order to exploit this mechanism, it is necessary that the zirconia dispersed particles are largely tetragonal and transformable. As shown by Lange (1982) and Heuer *et al.* (1982), the transformability depends on zirconia particle size, zirconia particle content, and zirconia stabilizer content. Moreover, the shape and crystallinity of the zirconia particles, their location and the question if they form a percolating network are crucial. The transformation toughness ΔK_{IC}^T of the composite can be roughly calculated using a slightly modified formalism according to McMeeking and Evans (1982).

$$\Delta K_{IC}^T = X \cdot V_z \cdot V_m \cdot E \cdot \sqrt{c \cdot \varepsilon_T / (1 - \nu)} \quad (1)$$

(X : transformation efficiency, V_z : zirconia content, V_m : transformed fraction, c = transformation zone size, ε_T : expansion due to phase transformation, ν : Poisson’s ratio, E : Young’s modulus).

Interaction of different effects makes the exact quantification however very complicated.

Small amounts of <10 vol% fine and well distributed zirconia particles can be added without the need to add stabilizer (typically yttria) (Lange, 1982). Transformation of these isolated zirconia particles can only be triggered by stress. Martensite plates formed in one zirconia particle cannot trigger transformation in adjacent grains, the shear component of the transformation is reduced by self-accommodation: a formation of twin shaped monoclinic domains in the grains (Lee *et al.*, 1994). In such a case, the maximum transformation efficiency is obtained (dilatation and shear component fully exploited, $X \sim 0.5$, such as in magnesia stabilized zirconia Mg-PSZ) (Kelly and Rose, 2002). As the transformability of an inclusion is size-related, the challenge in these materials is to produce materials with an almost monodisperse zirconia fraction which transforms at a defined stress. Still due to the limited zirconia content V_z (typically 10–20 vol%), the achievable toughness increase is moderate.

In ZTA materials containing larger fractions of zirconia, the zirconia particles are no longer isolated and one transforming particle may trigger transformation in an adjacent grain. The percolation threshold for this transition theoretically is in the range of 15–17 vol% zirconia (Balberg *et al.*, 2004). In this case the transformation efficiency should be drastically reduced as then transformation should become largely dilating ($X = 0.22$). Moreover, it becomes necessary to stabilize the zirconia dispersion with, e.g., yttria to prevent re-transformation to monoclinic during cooling (Sommer *et al.*, 2012a,b). The beneficial effect of the increase in V_z is therefore partially offset by the reduction of X (see Eq. (1)). The maximum toughness is typically achieved for compositions close to the percolation point. Other stabilizers than yttria never gained any importance for biomedical grade ZTA. ZTAs with ceria stabilized zirconia dispersions (12Ce-TZP) would require zirconia grain sizes of 1.5–2 μm to overcome the constraint of the alumina matrix (Grain size 3–4 μm) and become sufficiently transformable (Becher *et al.*, 1993).

A combined effect of microcracking and transformation stress is transformation induced microcracking (Shin *et al.*, 1999). In this case, microcracks (non-preexisting) are formed under applied load when the applied stress triggers transformation of tetragonal zirconia grains. Contrary to preexisting microcracks, the material contains initially no flaws and shows no progressive damage as long as the applied stress is low (under regular operation conditions) but is able to provide a toughness boost in catastrophic loading situations.

Residual stress

Without phase transformation, the inclusion of a high CTE tetragonal zirconia grain into a low CTE alumina matrix results in compressive stress for the matrix and tensile stress for the inclusion: e.g., in a ZTA containing 25 wt% of entirely tetragonal zirconia, the alumina matrix is under a hydrostatic compressive stress of 225 MPa (Gregori *et al.*, 1999). The direct dispersion toughening effect of the high CTE dispersion is however negligible due to the fine grain microstructure of biomedical ZTA (Taya *et al.*, 1990). Applied and residual stress are additive. Such a situation – a matrix under compressive stress – is beneficial to achieve high strength. Moreover, the tensile stress on the tetragonal zirconia dispersion – the composite in total is stress neutral – should facilitate its stress induced transformation.

In “real” ZTA materials, the latter effect is difficult to realize as keeping the entire dispersion tetragonal (considering a certain width of zirconia grain size distribution) practically requires severe over-stabilization. Such materials, e.g., with a dispersion of 3Y-TZP are typically strong but not tough as the tetragonal phase is mostly not transformable. In ZTA materials in which the zirconia partially re-transforms during cooling a certain monoclinic content is created associated by volume expansion. This volume expansion leads to tensile stress in the matrix, which counteracts the effect of the CTE mismatch (Gregori *et al.*, 1999). It was shown that an equilibrated strength-toughness characteristic is reached in a state where the matrix is stress neutral, i.e., a situation where CTE and transformation related volume expansion equilibrates (at ~22% monoclinic). The toughness maximum is typically obtained for a ZTA with an alumina matrix under slight tensile stress. Data from studies on hot pressed and pressureless sintered ZTA with biomedical grade recipe (17 vol% zirconia) support this assumption (Sommer *et al.*, 2012b; Kern *et al.*, 2016; Yildirim and Kern, 2019).

The state of residual stress not only affects the mechanical properties. Machining characteristics and behavior in as-implanted state are also strongly influenced. In an alumina matrix under tensile stress (at relative monoclinic zirconia contents of >25%), breakout of grains is facilitated. The detrimental effect to machinability was detected when trying to machine understabilized alumina – 17 vol% zirconia (Kern *et al.*, 2016). Pezzotti *et al.* (2008) showed that samples with low monoclinic content in as manufactured state formed a high fraction monoclinic after aging in vivo so that grain detachment was facilitated. Reviewing the properties of the biomedical grade materials of the leading manufacturer (higher phase stability after LTD in recent study by Pezzotti *et al.* (2010)) compared to earlier one by the same author (Pezzotti *et al.*, 2010) indicates that in recent years the manufacturer tended to retain a higher tetragonal phase content and sacrifice some toughness by finer microstructure and/or higher stabilizer content in favor of enhanced long term phase stability.

Third phases

Further “reinforcement phases” can be introduced into ZTA. Two leading companies use zirconia toughened composites (ZTC) which contain a few percent of in situ formed strontium hexaaluminate ($\text{SA6} = \text{SrAl}_{12}\text{O}_{19}$), a phase with an elongated plate or rod shape in addition to the zirconia dispersion. Despite the fact that these ZTCs do have extraordinarily high strength, the simplistic explanation that the effect is due to crack bridging and crack deflection which is put forward by the manufacturers (Kuntz, 2006) may be challenged due to basic fracture mechanics considerations (He *et al.*, 1994). Hexaaluminates have lower Young’s modulus than the alumina matrix (Schmid *et al.*, 1999), therefore a crack proceeding in the alumina matrix will never be deflected at a strong alumina SA6/interface hit orthogonally by the crack, this may happen only if the platelets are hit under a very flat angle. Still, the SA6 has higher CTE than alumina which should slightly increase toughness and the slightly lower elastic constraint may improve transformability of the zirconia dispersion. For ZTA containing 24 vol% zirconia (1.4Y) reinforced with cerium hexaaluminate ($\text{CeAl}_{11}\text{O}_{18} = \text{CA6}$), no crack deflection was found. Still the platelet reinforced materials had higher toughness and resistance to subcritical crack growth, however at lower strength and toughness (Kern, 2013). For material with 10 vol% unstabilized zirconia and 5 vol% platelet addition, abnormal grain growth and a shift from an inter-type to an intra-inter type microstructure at high sintering temperatures were observed (Kern, 2012b). Usually, any additional separate and insoluble phase may change the residual stress distribution and restrict grain growth which helps maintaining a fine microstructure during firing (Kim and Kriven, 2008; Palermo *et al.*, 2011a).

In order to develop a ZTA material with tailored strength-toughness characteristics for a demanding application such as biomedical implants, it is important to know that depending on material design and processing conditions all reinforcement effects are operative simultaneously.

The Set of Requirements and the Resulting Current Standard ISO6474-2

The effective requirements to ZTA implants are different with respect to the patient, his activity, his weight and the type of articulated joint (hip, knee, shoulder, etc.). In the case of hip, the requirements are definitely lower than in case of the knee. The ball/socket joint in the hip is preferably loaded compressively. However, a modern prosthesis system is based on a conical taper with press-fit of the ball-head; i.e., by this combination, the ball-head is under tensile stresses. Therefore, high mechanical strength properties are required for the ball-head. The joint (ball and socket joint) is in plane contact, so that the contact pressure per unit area is relatively low. In fact, the experience with the first generation of alumina THR prostheses – which had only moderate strength – leads to the assumption that the vast majority of implanted components survived. Regular loading conditions can be endured over long periods by alumina joints with proven track record which are less strong (~400–500 MPa) and less fracture

resistant ($K_{IC} < 4 \text{ MPa}\sqrt{\text{m}}$) than biomedical grade ZTA (Willmann, 1996). It should however be noted that 30 years ago hip implants were typically implanted to older patients with a lower level of activity.

Point or line load can however occur when the ball is withdrawn from the socket and chafing over the edge of the ceramic socket when slipping back (Uribe *et al.*, 2013). In case of ceramic/ceramic pairings, this can cause (even if it happens much less frequently than the regular loading) much more severe stripe wear and in rare cases, even chipping of the edge of the socket may occur. In case of larger balls, this effect can be reduced, as the articulation angle is larger for larger joints. While wear and release of wear debris is an important failure criterion for ceramic/polymer joints, the wear in ceramic/ceramic pairs is negligible. Rahaman *et al.* (2007) quoted wear rates of $200 \mu\text{m}/\text{year}$ for Co-Cr/UHMWPE, this value is reduced to $< 100 \mu\text{m}/\text{year}$ for alumina or zirconia articulating. Alumina/alumina couples show wear rates of $< 5 \mu\text{m}/\text{year}$. Similar tendencies which are however not comparable due to different wear units were obtained by El-Hajjar *et al.* (2013). They found a wear of $0.74 \text{ mm}^3/10^6$ cycles for alumina/alumina, $0.14 \text{ mm}^3/10^6$ cycles for ZTA/ZTA and $0.06 \text{ mm}^3/10^6$ cycles for ATZ/ATZ all ceramic joints.

Attaching the ball on the metal stem is a safe procedure as soon as the surgery procedures by the implant manufacturers are carried out properly. Moisture or any kind of debris such as small bone fragments in the gap between cone and ball must in any case be avoided. The latter cause tensile stress which can reduce the strength of the taper/ball combination drastically.

The knee is the most demanding component. The loading conditions are line or point load. It should be specified that the femoral and tibia part can be made of ceramics. They are, however, separated by a rotating or fixed UHMWPE polymer insert which drastically reduces the Hertzian load due to its low elastic modulus. Metal knee implants are relatively thin walled, which is no problem due to the ductility of the material. Extensive removal of tissue for implantation is to be avoided. The available space is limited which requires a design with low wall thickness and consequently a ceramic material with superior strength. Fixation of a ceramic knee implant is a tricky procedure even for skilled surgeons as the standard procedure for metal components – driving by impact – has to be carried out with utmost care to avoid damage. For this reason, no producer ever dared to commercialize knee implants made of alumina, the application of ceramic knee joints required materials with a higher strength and an improved fracture resistance. These prerequisites are only possible with ZTA or zirconia (Y-TZP). Requirements to knee implants are included in the standard DIN EN ISO 21536:2009. In the meantime, the first successful clinical studies were published. Meier *et al.* (2016) reported burst strength of 11.8–13.5 kN for the tibia part of the prosthesis made of BioloX Delta®.

Besides the mechanical stability, any material containing zirconia is viewed suspiciously since a couple of zirconia joints failed by LTD in the 1990s (Chevalier, 2006; Piconi *et al.*, 2006). LTD was discovered by Kobayashi years before but nobody seriously considered that the effect would happen with measurable speed at blood heat (Kobayashi *et al.*, 1980). Anyway due to some imperfections along the process chain of implant manufacturing, it happened and many patients suffered from sudden joint failure and the need to endure surgery once again. The claims for damage were severe and yttria stabilized zirconia was more or less banned for endoprosthesis applications even though newly developed recipes showed drastically improved LTD stability. Testing for LTD, a spontaneously happening phase transformation from tetragonal to monoclinic in contact with polar liquids (water, body fluids) has become a standard for qualifying biomedical grade ZTA materials. This includes not only the phase transformation as such but also mechanical tests, wear tests and fatigue tests after accelerated hydrothermal ageing. The requirements to ZTA materials are summarized in ISO standard 6474-2. Besides X-Ray diffraction and RAMAN spectroscopy tests to analyze the changes in the phase composition recently more sophisticated methods were applied. Pezzotti (2014) showed by cathodoluminescence measurements that the oxygen sub-lattice in alumina and zirconia (3Y-TZP) materials behave completely different if exposed to water over a long time. While alumina creates oxygen vacancies which can then be occupied by cations of lower valence such as Ca^{2+} and Mg^{2+} , Y-TZP actually eliminates a part of oxygen vacancies introduced by stabilizing with Y^{3+} – with the well-known detrimental consequences regarding LTD resistance. For alumina/zirconia composites, Pezzotti stated a strong influence of minor amounts of dopants such as chromia and titania (present in products by different manufacturers) which may have a strong and adverse influence on the phase stability and thereby the LTD resistance of ZTA.

Table 1 shows a selection of the most important requirements to composition, microstructure, and mechanical properties. Concerning the composition, besides the typical ingredients alumina, zirconia, and yttria to stabilize the zirconia phase, further constituents may be contained including projected additives (such as chromia, titania, or strontium oxide to create hexaaluminate platelets) but also allows a certain amount of impurities which are typically contained in the starting powders.

At first sight, these minimum requirements are just slightly better than a high quality alumina. It should however be mentioned that the best biomedical grade ZTA materials by far outperform the standard.

Manufacturing

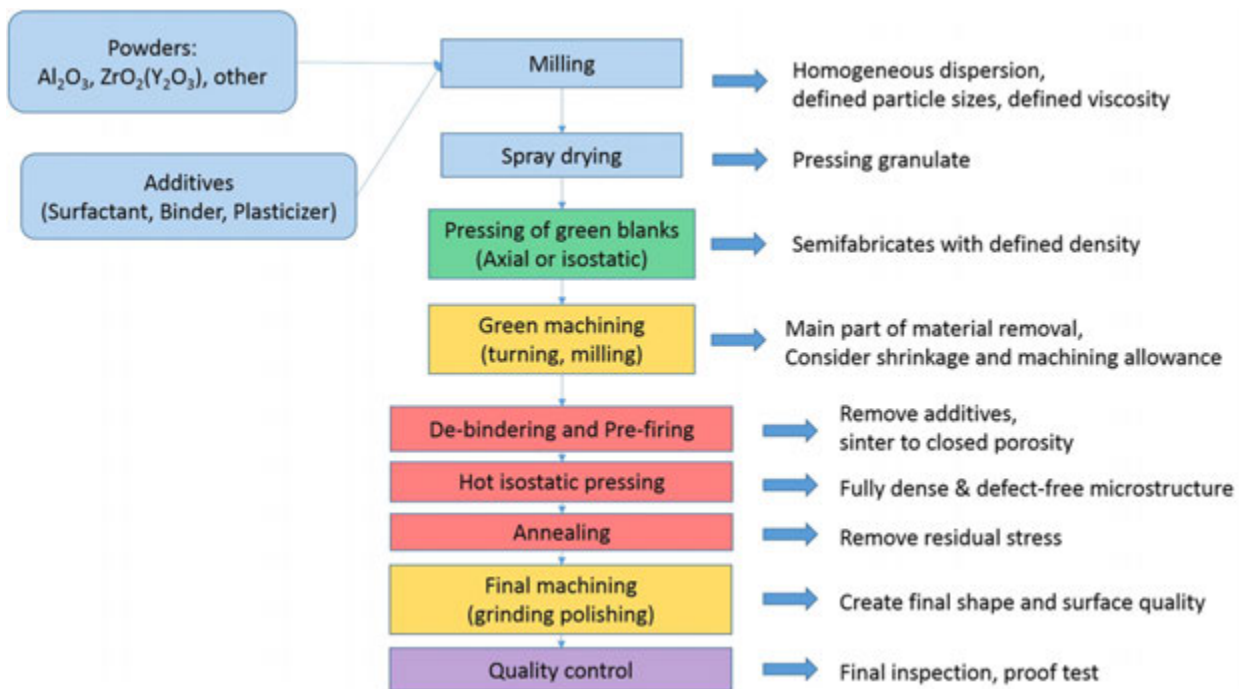

Despite the fact that several alternative routes have been tried to manufacture biomedical grade ZTA, the prevalent shaping technology is pressing of blanks and subsequent green machining. The complete process chain is shown in Fig. 7. The processing steps are strongly correlated to each other, so that the previous steps influence the subsequent ones. Therefore, inaccuracies or introduction of defects in one step may lead to detrimental consequences in the following steps which may result in insufficient quality or to increase in effort in the subsequent operations. As final machining represents the most costly part of the chain, all previous process steps must be carried out in such a way as to minimize the final machining effort.

Implants for, e.g., hip or knee are biomedical components and are therefore subject to strict regulations (e.g., by FDA). This means that once the material is authorized the whole production cycle is fixed and cannot be altered without re-approval by the

Table 1 Requirements according to ISO6474-2 type X

Property	Requirements acc. ISO6474-2
Density	$\geq 99\%$ of theoretical
Alumina grain size	$\leq 1.5 \mu\text{m}$
Zirconia grain size	$\leq 0.6 \mu\text{m}$
Bending strength	$\geq 600 \text{ MPa}$
Fracture resistance	$\geq 4 \text{ MPa}\sqrt{\text{m}}$
Vickers hardness	$\geq 16 \text{ GPa}$
Young's modulus	$\geq 320 \text{ GPa}$
Cyclic fatigue	No failure at 10^7 cycles at 400 MPa load
Hydrothermally aged strength	$\geq 600 \text{ MPa}$, $< 20\%$ strength loss compared to as processed condition
Hydrothermally aged fatigue	No failure at 10^7 cycles at 320 MPa load
Hydrothermally aged wear	$\leq 20\%$ wear increase compared to as processed condition
Composition	60–90 wt% alumina 10–30 wt% ZrO_2 ($< 5\% \text{ HfO}_2$) $< 10 \text{ wt}\%$ projected additives 0.2 wt% Impurities such as, e.g., SiO_2 , CaO , Na_2O

Note: Data extracted from ISO standard ISO6474-2.

**Fig. 7** Process chain for manufacturing of biomedical grade ZTA.

regulatory agency. Due to high effort of time and money re-approvals are in most cases economically not justified and, therefore, very rare.

Typically submicron size alumina and nanoscale zirconia are used as starting powders. Depending on the zirconia fraction, a stabilization of the zirconia with yttria is required (at $> 10 \text{ vol}\%$ zirconia) (Lange, 1982). Besides the main mandatory constituents some manufacturers add “projected additives” such as magnesium oxide, titanium oxide, strontium oxide and chromium oxide either to control grain growth, form second phases such as hexaaluminates or to stabilize zirconia (Pezzotti, 2014).

As structural homogeneity (i.e., a homogeneous dispersion of zirconia in the microstructure) is a crucial property, the compounding procedure is the key to achieve the desired properties such as mechanical strength and LTD resistance.

Mixing and milling steps represent the state of the art, here the challenge is to develop a surfactant system appropriate for the mixed suspensions containing powders of different surface chemistry. Fig. 8 shows some examples of Zeta potential curves of some alumina and zirconia powders (Yildirim and Kern, 2019). It can be seen that the alumina (APA0.5, green) and one of the zirconia powders (partially stabilized 2Y-TZP, IN-2Y, red) show almost identical trends, a point of zero charge at $\text{pH} = 5.5$ and sufficient

Fig. 8 Zeta potential of some alumina and zirconia powders. Redrawn, two data sets added Yildirim, N., Kern, F., 2019. Mechanical properties and ageing resistance of slip cast and pressurelessly sintered ZTA – The influence of composition and heat treatment conditions. *Sci. Sinter.* 51 (3), 1–14.

stability ($\zeta > 130 \text{ mV I}$) at $\text{pH} > 7.5$, while the two other monoclinic zirconia powders (TZ0 and CZE-M1) exhibit a point of zero charge at $\text{pH} = 3\text{--}3.5$ and a sufficient stability at $\text{pH} > 5.5$. Some of the projected additives such as magnesia and strontium oxide have a very basic character which would negatively affect the suspension stability. They may be added as aluminates (e.g., MgAl_2O_4) or zirconates (e.g., SrZrO_3) (Cutler *et al.*, 1991) as these ternary phases have a more favorable surface chemistry. Leriche and coworkers have shown that while yttria free recipes can also be dispersed in the acidic regime, yttria containing recipes should be prepared in the alkaline regime ($\text{pH} 10\text{--}11$) to avoid partial solubilization of yttria (Leriche *et al.*, 1992).

A good overview on organic additives for ceramics processing was recently published by Aimable and Chartier (2020). Today either commercially available electrosteric dispersants such as polyacrylates supplied under the brand names Darvan C-N by Vanderbilt minerals or Dolapix from Zschimmer & Schwarz are used or manufacturers have their own proprietary recipes.

At the technical scale, the compounding step is performed with batches of hundreds of kilograms of powder, which are mixed and milled in agitator bead mills with Y-TZP milling media. For this purpose, the powder blends are dispersed in de-ionized water using the aforementioned dispersants and milled, either by recirculation of the dispersion over the milling chamber of the bead mill, or by oscillating the suspension between two stirred storage tanks. The latter method is more complicated but offers the opportunity to adjust a narrower residence time distribution and thereby a potentially better homogeneity.

The stabilized suspension is blended with the other additives such as binders and plasticizers. The binders – typically either polyvinylalcohol (PVA) or acrylates – are required to provide the sufficient green strength for handling and green machining. Plasticizers make the ready-to-press-powder more compliant. The ready-to-press-powder is subsequently manufactured by spray drying to produce a granulate with an average diameter of $\sim 60\text{--}80 \mu\text{m}$, a more or less spherical shape, good free flowing properties and a well-defined bulk density (Naglieri *et al.*, 2013b). This well-defined bulk density is mandatory as in the subsequent pressing processes the metering of the granulate – at least in case of axial pressing is performed volumetrically.

Dry pressing is carried out either by uniaxial pressing which leads to cylindrical blank shapes or by cold isostatic pressing (CIP) which is capable to produce a roughly pre-shaped ball geometry. During the pressing process, it is necessary that the granules are completely crushed. In fact, remaining granule artefacts left in the microstructure of the green compact can produce detrimental effects in the mechanical properties of the sintered pieces. In order to minimize density gradients and resulting shape inaccuracies, uniaxial pressing is carried out by double sided pressing in steel molds, where the punches are often cemented carbide materials to reduce wear. CIP can be carried out either by wet- or dry bag technology. For mass production, typically dry-bag pressing is carried out in pre-shaped compressible polymer molds (e.g., polyurethane) which are capable to manufacture shapes very close to the desired final shape.

Fig. 9 shows how a cold isostatic pressed spherical green body is placed on a tray by a vacuum-assisted handling system after removing it from the press. As can be seen, apart from a ring-shaped seam the green compact is an almost perfect sphere.

Moreover, the green density of the pressed blanks has to be adjusted within an extremely narrow range with respect to the subsequent machining operations. This requires a strict control of the recipes for the pressing granulate and the protocols for the pressing parameters. Both uniaxial and isostatic pressing have their pros and cons.

Uniaxial pressed cylindrical blanks are much easier to mount and green machine due to their well-defined dimensions. It should however be considered that density distribution in an uniaxially pressed cylinder is always inhomogeneous, the top and bottom which were in contact with the punches are denser than the material in the center (press-neutral-zone). Therefore, by this pressing method, the machine parameters have to be adjusted that the press neutral zone is shifted within the cylindrical part to

Fig. 9 Near net-shape cold isostatic pressed green bodies. Image courtesy of Mathysmedical (CH).

Fig. 10 Green machining of a ball. Image courtesy of Mathysmedical (CH).

the very low end. Clamping shall take place at the very low end of the cylinder. This approach finally guarantees a homogeneous green density for the final part after machining.

CIPed blanks (especially made by wet-bag processes) have more irregular shapes which makes correct mounting on the turning machines a bit more complicated. However, using CIPed blanks saves a lot of precious raw material as the blank already has a pre-shape. For a ball of 40 mm final diameter, it may be estimated that considering a loss fraction of 50% starting from axially pressed and only 15% if starting from near net shape CIP blanks, the material saved amounts to ~ 40 g per piece (taking into account that 1 kg of ready-to-press powder in production is about EUR 100.–, savings by isostatic near-*net*-shape pressing are significant).

Fig. 10 shows the green machining (turning) of a ball. Machining is made in dry state, and milling dust has to be extracted by suction. Due to the highly abrasive character of the green compact typically diamond coated milling tools are used. [Klocke *et al.* \(1997\)](#) showed that despite the higher price of diamond coated tools compared to plain cemented carbide tools, the cost per machined piece can be cut by factor of three. As besides the machining of the outer contour the conical taper also has to be machined out, it is necessary to change the clamping from left to right after finishing the milling operation from one side. Typically, automated lathes equipped with two opposite clamping units and automatic tool changer are used. Proper selections of tools, clamping devices and machining strategies are essential to obtain defect-free green-machined semi fabricates ([Margarindo *et al.*, 2017](#)). Contrary to manufacturing of less demanding structural ceramic parts, recycling of the milling dust is not possible due to the inherent risk of contaminating the ready-to-press powder with debris from the cutting tools. The economic challenge in

Fig. 11 Grinding of a ceramic liner. Image courtesy of Mathysmedical (CH).

green machining is to create a geometry extremely close to the final shape (considering sintering shrinkage) so that final machining can be reduced to a minimum.

Non rotationally-symmetric parts require more complex machining operations. Especially complex shaped surfaces of knee-implants could not be economically machined until very fast program-controlled 5-axis milling machines were set up which were capable to machine complex shapes and create a smooth enough surface. Near-*net*-shape technologies capable to form such complex geometries would be highly desirable to cut production cost and reduce waste. Technologies considered were slip casting (Naglieri *et al.*, 2013a), direct coagulation casting (DCC) (Graule *et al.*, 1995) and application of ceramic injection molding (Abou El-Ezz *et al.*, 2011). However, to date no net-shaping technology was developed that was able to produce components for THR and TKR of the required strength and reliability.

Machined components are typically automatically mounted on suitable kiln furniture, balls are typically sintered on spherical sockets.

In order to meet the high requirements concerning strength, toughness, wear resistance and LTD resistance, the ceramics should be almost perfectly defect-free and have a fine-grained and extremely homogeneous microstructure (Chevalier *et al.*, 2007, 2009). The heat treatment is typically multi-stage process combining atmospheric sintering and hot-isostatic pressing ("sinter-HIP"). In the first sintering cycle under atmospheric conditions, the first step is burning out of the organic additives at low temperature ($\sim 600^\circ\text{C}$). After debinding, the components are sintered to closed porosity; i.e., density above $\sim 94\%$. Preferably, the density of the pre-fired ceramic part should be between 96% and 98%. Depending on recipes this requires a sintering temperature of $\sim 1400\text{--}1500^\circ\text{C}$. Basically it is no problem to fully densify alumina-zirconia composites with submicron size microstructure below 1500°C by pressureless sintering in air (Palmero *et al.*, 2011b). In the next step, these pre-fired ceramics are transferred into a hot isostatic press. As the pre-firing has created a gas-tight microstructure, the sinter-HIP cycle can be carried out without the need to apply a pressure transducing shell as in classical HIP. Applied pressures are typically in the range of 100 MPa, the atmosphere is typically argon. The temperatures are approximately in the same range as in pre-firing. This pressure assisted sintering cycles is vastly capable to remove remaining structural defects (Bocanegra-Bernal *et al.*, 2009).

The benefit of post-HIPing was manifested in a drastic increase in reliability. According to a report of CeramTec, the failure rate of Biolox® (alumina) femoral heads decreased from 0.026% to 0.004% from the first generation of relatively coarse grained pressureless sintered alumina femoral heads to the third generation of post-HIPed fine grained materials (Willmann, 1996). As the reducing atmosphere creates oxygen vacancies and as the pressure assisted sintering may create residual stresses typically a third heat treatment cycle is carried out under atmospheric conditions to re-oxidize and anneal the ceramics. It has to be stated that the major benefit achieved with HIPing has to be seen in combination with proof-testing.

Now the materials are ready for final machining. Fig. 11 shows the grinding of the outer side of a ceramic liner (pelvic part). Due to the high hardness and abrasion resistance of ZTA materials, this requires the use of diamond tools for grinding and diamond suspensions for polishing. Compared to alumina machining of the hard, tough and fine grained ZTA material is much more challenging. The transition from ductile to brittle in grinding of ceramics is observed at a value of

$$h_{crit} = 0.15(E/H) \cdot (E/K_{IC})^2 \quad (2)$$

(with E = Young's modulus, H = Vickers hardness, K_{IC} = fracture resistance). To obtain brittle behavior which enables machining at high speed, a typical biomedical grade ZTA ($E = 356 \text{ GPa}$, $H = 18 \text{ GPa}$, $K_{IC} = 6 \text{ MPa}\sqrt{\text{m}}$) requires an advance rate h_{crit} three times higher than a typical biomedical grade alumina ($E = 385 \text{ GPa}$, $H = 18 \text{ GPa}$, $K_{IC} = 3.5 \text{ MPa}\sqrt{\text{m}}$). This increases the requirements to machines and tools drastically (Klocke and König, 2005). At the same time, it should be considered that even though brittle conditions are required for acceptable machining speed during the roughing step, machining in the brittle regime always means a damaging of the surface. As ZTA contains transformable tetragonal zirconia, there is always a phase transformation

Fig. 12 Measurement of the geometry by tactile method. Image courtesy of Mathysmedical (CH).

of the zirconia from tetragonal to monoclinic in the processed zone under roughing conditions (Denkena *et al.*, 2017). Such a transformed zone is typically under high compressive stress and desired for many mechanical engineering applications. The correlation between residual stress, strength and machining is very complex and non-linear (Xu *et al.*, 2010).

In contrast, in case of ZTA for biomedical applications a machining induced phase transformation is not desired in the final component as it is feared that existing monoclinic phase nucleates subsequent low temperature degradation processes. Proper adjustment of machining parameters, choice of tool geometries, cooling liquids and lubricants is required to achieve the necessary surface quality for a ceramic-polymer or all ceramic couple and to avoid machining induced LTD processes. Hence, there are no publications giving details on this special issue, and the knowledge generated in the companies in this field over generations that gives power over competitors was always kept secret. It is known that even companies with decades of experience in machining alumina or zirconia had a hard time machining the hard and tough ZTA material and it took time and financial effort to process a set of appropriate and profitable machining parameters.

Quality control has become an integral part of the production cycle in order to persistently guarantee the specified material properties and in order to meet the requirements of the regulatory agencies. Fig. 12 shows the tactile measurement of the taper geometry of ceramic balls.

Different companies use various exactly specified test protocols including, e.g., automated measurement of geometrical tolerances, optical inspection, application of fluorescent crack detection solvents, regular measurement of randomly picked control samples and proof tests in which every single component is checked with a specified load which exceeds the load expected in application. Failure of a single component in the proof test may lead to a blocking of the whole production batch until the reason for failure is detected. Laser marking of the manufactured components allows traceability of the components.

Conclusion

Biomedical grade ZTA materials have today reached a high degree of reliability and maturity. Manufacturing cycles were successively refined over the last two decades allowing to manufacture materials with very high strength, abrasion resistance and LTD stability. This has allowed for extending the range of applications from the classical total hip arthroplasty to the knee which is mechanically more demanding, the shoulder and other smaller joints. However, it is difficult to predict what the next stage of development will be, a modified more sophisticated ZTA ceramic or a completely different material system such as silicon nitride which has recently entered the market.

This is an update of Attfield, J.P., 2001. Phosphates. In: Buschow, K.H.J., Cahn, R.W., Flemings, M.C., *et al.* (Eds.), *Encyclopedia of Materials: Science and Technology*. Oxford: Elsevier, pp. 6896–6901.

Introduction

Phosphates are materials containing oxoanions of phosphorus (V), ranging from the simple orthophosphate group PO_4^{3-} through ring and chain anions to infinite networks. Oxoanions of phosphorus in lower oxidation states such as phosphite, HPO_3^{2-} , are also known. Many solid phosphates have been prepared or are found as minerals. Their diversity results from variations in the phosphate species, the large number of cations to which they may be coordinated, and the presence of other anions or molecules, notable H_2O . Their chemistry and properties are similar to those of solid silicates (see *Acid Catalysts, Clays, and Zeolites*). Background information on the chemistry of phosphates and related phosphorus species can be found in [Corbridge \(1974\)](#) and [Kanazawa \(1989\)](#).

Phosphate Anions

Solid phosphates are conveniently classified according to the anions they contain. Orthophosphates contain isolated phosphate tetrahedrons, but these can also be linked through P–O–P bridges to give a range of condensed phosphate anions ([Fig. 1](#)) ([Durif, 1995](#)).

Orthophosphates, (di)Hydrogen Phosphates

The orthophosphate (often shortened to “phosphate”) group, PO_4^{3-} , is the most common phosphorus oxoanion. All four oxygen atoms are usually coordinated to cations in solid orthophosphates leading to strongly bonded, extended structures. The acid orthophosphate

Fig. 1 Isolated P – O Structures Including Ortho, Pyro, Poly, and Ultra Phosphates. Description of the Geometry of the Basic Unit of the PO_4 Tetrahedron.

anions hydrogen phosphate, HPO_4^{2-} , and dihydrogen phosphate, H_2PO_4^- , are also found in many materials. Almost every metallic element forms an orthophosphate, and a range of oxidation states is stabilized for transition elements, e.g., from V^{II} to V^{V} in $\text{NaV}^{\text{II}}\text{V}^{\text{III}}_2(\text{PO}_4)_3$, $\text{V}^{\text{III}}\text{PO}_4$, $\text{V}^{\text{IV}}\text{O}(\text{H}_2\text{PO}_4)_2$, and $\text{V}^{\text{V}}\text{OPO}_4$. Mixed anion orthophosphates are sometimes found, e.g., $\text{Ca}_2(\text{PO}_4)\text{F}$, $\text{Fe}_2(\text{PO}_4)\text{O}$, $\text{LiMn}(\text{PO}_4)(\text{OH})$, and $\text{Ca}_5(\text{PO}_4)_2(\text{SiO}_4)$. Solid solutions in which the orthophosphate group is partially substituted by orthoarsenate, vanadate, and silicate groups further extend the range of possible phases.

Pyrophosphates, Diphosphates

The pyrophosphate anion $\text{P}_2\text{O}_7^{4-}$, consists of two phosphate tetrahedrons linked through a common oxygen atom. This bridging oxygen does not coordinate even to highly charged cations. Pyrophosphates are also known as “Diphosphates”. They often result from thermal treatment of orthophosphates. Many pyrophosphates are known and variations in composition and structure are similar to those for the orthophosphates.

Polyphosphates

Linking phosphate tetrahedra into chains through two vertices results in polyphosphate anions, $\text{P}_n\text{O}_{3n+1}^{(n+2)-}$, also known as oligophosphates. Finite chains containing up to six tetrahedra have been found in the solid state. They become less common with increasing n . Cyclophosphates (cyclopolyphosphates), $\text{P}_n\text{O}_{3n}^{n-}$, contain rings of up to 12 tetrahedra, but those with three, four, and six units are most common. Infinite catenaphosphates chains, $(\text{PO}_3^-)_\infty$, are formed at high temperatures. Polyphosphates sometimes adopt layered structures which can intercalate molecules in the interlamellar spaces, e.g., organic amines are intercalated by the triphosphates $\text{MH}_2\text{P}_3\text{O}_{10} \cdot 2\text{H}_2\text{O}$ ($\text{M} = \text{Al}, \text{Cr}, \text{Mn}, \text{Fe}$).

Ultraposphates

These contain two- and three-connected phosphate tetrahedra and have stoichiometry $\text{P}_n\text{O}_{3n-1}^{(n-2)-}$, where $n = 4, 5, 6$, and 8. The unique cage phosphate anion $\text{P}_8\text{O}_{23}^{6-}$ is the only example of a molecular ultraposphate anion. The other species form infinite framework anions in which charge-compensating cations reside. Ultraposphates are anhydrous, as the P–O–P bridges between three-connected phosphate tetrahedra are susceptible to hydrolysis. The lanthanide ultraposphates MP_5O_{14} are notable laser materials.

Mixed-Anion Phosphates

The Mixed-Anion Phosphates (MAP) contain two kinds of phosphoric anions having different degrees of condensation. Pyrophosphates-orthophosphates are the main family of MAP. These phases are crystallized mainly e.g., $\text{LiMg}_3(\text{PO}_4)(\text{P}_2\text{O}_7)$ (Kim *et al.*, 2015) or amorphous e.g., $(\text{Ca}_y\text{Na}_z\text{H}_{3+y-2y-z})(\text{PO}_4)_{1-x}(\text{P}_2\text{O}_7)_x \cdot n\text{H}_2\text{O}$ (Soulié *et al.*, 2016).

Preparation of Solid Phosphates

Preparative routes for solid phosphates are typical of those used in materials chemistry. Reactions in which cations and phosphate anions are combined can take place in solution under normal or hydrothermal pressures, or by direct combination at high temperatures to overcome kinetic barriers. Hydrothermal, flux growth, and chemical vapor transport techniques are used to facilitate crystal growth. Transformations of phosphates into new structures can be achieved thermally or through ion-exchange reactions.

Solution and Hydrothermal Methods

Many phosphates of soluble cations, e.g., alkali and alkaline earth metals, ammonium, can be deposited from aqueous solutions, and this method can be used for crystal growth. Acid phosphates such as KDP (KH_2PO_4) (see Section “Ferroics”) may be prepared by partial neutralization of phosphoric acid with metal hydroxides or carbonates. Insoluble phosphates can be precipitated by mixing cation and phosphate solutions and condensed phosphates can be prepared from polyphosphoric acids, made by adding a small amount of water to P_2O_5 . The solubility of phosphates of highly charged cations increases with temperature and pressure, and so hydrothermal conditions are used to obtain more crystalline products, as well as many phases not formed at atmospheric pressure (see *Hydrothermal Synthesis*). This method is also used to grow large single crystals of materials such as KTP (see Section “Nonlinear Optical Materials”). Microporous metal phosphates are prepared in hydrothermal bombs using hydrated cations or quaternary ammonium species as templates to direct the porous framework (see Section “Microporous Materials”). Ion-exchange reactions in solution can be used to modify phosphates containing mobile cations, e.g., treatment of the cyclophosphate $\text{AgP}_6\text{O}_{18} \cdot \text{H}_2\text{O}$ with aqueous NaCl gives $\text{NaP}_6\text{O}_{18}$.

Thermal Treatments and Flux Growth

Heating well-ground mixtures of a metal oxide or salt and P_2O_5 or a phosphate source such $NH_4H_2PO_4$ is a convenient route to many anhydrous phosphates and gives a good control of stoichiometry. Gentle heating of hydrated phosphates gives many anhydrous materials and further thermal decomposition often yields new phases; in particular, dehydration of acid phosphates can result in condensed phosphate anions. Many phosphates melt congruently enabling crystals to be grown by slow cooling and phosphate glasses can be obtained via a rapid quench. Excess phosphate or water may be added to promote flux growth of crystals, e.g., lanthanide ultraphosphate crystals, MP_5O_{14} , are grown by cooling $M_2O_3 - P_2O_5 - H_2O$ melts from 400 to 500°C to room temperature.

Vapor Transport

Chemical vapor transport (see *Chemical Vapor Deposition*) can be used for a variety of anhydrous metal phosphates at temperatures around 1000°C using Cl_2 or I_2 as the carrier gas, through the formation of volatile halides and oxyhalides. This has been used to grow crystals of several phosphates, e.g., $TiPO_4$, $Fe_2P_2O_7$, RhP_3O_9 .

Sol-Gel Methods

Sol-gel methods using phosphate alkoxide precursors $(PO(OR)_3)$ (Livage *et al.*, 1992) or other sol-gel methods (Styskalik *et al.*, 2017) are reported in the literature. Nevertheless, the synthesis of phosphate glasses by sol-gel methods is still a challenge. The difficulty is induced by the undesired precipitation (quick hydrolysis) instead of reaching a gelation step considered as necessary to obtain glasses. Other precursor like $(PO(OH)_{2x}(OBu^n)_{2-2x})$ (with $x = 0$ or 1) has also been studied (Pickup *et al.*, 2007) in order to control hydrolysis.

Characterization of Phosphates

Solid phosphates range from being highly crystalline to glassy and the usual structural techniques of X-Ray or neutron diffraction and electron microscopy can be used to characterize them. Vibrational and NMR spectroscopies are both very useful for studying solid phosphates, especially poorly crystalline materials (Brow, 2000).

Both IR and Raman spectroscopies are used to study the vibrations of P–O bonds in solid phosphates (Rey *et al.*, 2014; Rulmont *et al.*, 1991). The features in the P–O stretching region (700–1400 cm^{-1}) are of greatest diagnostic use. Pyro- and polyphosphates are distinguished from orthophosphates by the vibrations of the P–O–P bridges, and the (–P–O–) rings in cyclo n phosphates give characteristic vibrations in the 600–850 cm^{-1} region.

NMR spectroscopy is extremely useful for studying phosphates (Kirkpatrick and Brow, 1995), as the ^{31}P nucleus has a spin of 1/2 and is 100% abundant. The magic angle spinning technique (MASNMR) is used to obtain highly resolved spectra from solid phosphates. The isotropic ^{31}P chemical shifts move to high-field values with increasing connectivity of phosphate tetrahedra and increasing charge on the coordinated cations, enabling different local environments in disordered materials to be identified. Paramagnetic cations can give a large contact or pseudocontact shift and may broaden the ^{31}P resonance. MASNMR can also be used to study kinetic processes, such as the crystallization of the solid phosphates from solution.

Phosphate Materials

Many phosphate structures are rigid, resistant to chemical attack, and can be thermally stable up to temperatures above 1000°C, giving rise to useful structural properties such as hosting mobile ions or molecules. Low absorption in the UV-visible region results in uses as optical materials. Many solid phosphates occur as minerals and biominerals. Main classes of phosphate materials are described below.

Fast Ion Conductors

Appreciable ionic conductivity is found in open framework or layered materials containing mobile cations (see section “Fast Ion Conductors”). A variety of crystalline phosphates are good ionic conductors, notably NASICON (NA Super Ionic CONductor) solid solutions $Na_{1+x}Zr_2(PO_4)_{3-x}(SiO_4)_x$ (Fig. 2) which have very high sodium ion conductivities in the range $1.8 < x < 2.2$. Many ion-exchanged derivatives and substituted NASICON frameworks are known, e.g., $AM_2(PO_4)_3$ ($A = Na, Ca, Sr, Ba$; $M = Ti, Mo$).

Many phosphates form layered structures (see Section “Intercalation Hosts and Ion Exchangers”) leading to high cation mobilities within the interlamellar spaces. Hydrated acid phosphates have high hydrogen ion conductivities, e.g., conductivities of 10^{-3} – $10^{-5} \Omega^{-1} cm^{-1}$ in $\alpha - Zr(HPO_4)_2 \cdot H_2O$ at room temperature. (The dispersion in these values reflects slight variations in the water content, as proton exchange between H_3O^+ cations enhances the conductivity.) Very high conductivities of $\sim 10^{-2} \Omega^{-1} cm^{-1}$ at 300K are also found in hydrogen uranyl phosphate.

Fig. 2 The structure of NASICON, $\text{Na}_{1+x}\text{Zr}_2(\text{PO}_4)_{3-x}(\text{SiO}_4)_x$, typifies the features of many metal phosphate materials. A rigid framework of corner-sharing ZrO_6 octahedra (cyan) and phosphate/silicate tetrahedral (orange) contains a network of connected pores through which the sodium cations (purple) migrate.

Fast ion-conducting surface phase in LiFePO_4 controlled off-stoichiometry (e.g., $\text{LiFe}_{1-2y}\text{P}_{1-y}\text{O}_{4-\delta}$, $y = 0.05$) allows to create battery materials for ultrafast charging and discharging (full battery discharge in 10–20 s) (Kang and Ceder, 2009). Improved LiFePO_4 is a commercial battery material whose practical capacity (165 mAh g^{-1}) and whose rate capability 60%–80% is excellent (Etacheri *et al.*, 2011).

Rapid cooling of phosphate melts gives glasses, some of which have appreciable ionic conductivities (Martin, 1991). $\text{M}_2\text{O} - \text{P}_2\text{O}_5$ glasses ($\text{M} = \text{Li, Na, K, Rb, Cs, Ag}$) containing at least 30% M_2O are stable and have high M ion conductivities which are enhanced by the addition of M halides. It has been proposed that microphase separation occurs in $\text{AgPO}_4 - \text{AgI}$ glasses giving small regions of highly conducting $\alpha\text{-AgI}$. The glassy matrix suppresses the structural phase change that quenches the ionic conductivity of AgI below 146°C . The superionic glasses formed by doping AgI into glasses are also noted $\text{AgI}_x(\text{AgPO}_3)_{1-x}$ (Sidebottom, 2000).

Intercalation Hosts and Ion Exchangers

Many phosphates adopt layered structures in which strong M–O–P bonding is present within rigid layers, but only weak electrostatic or hydrogen bonding occurs between layers. Ions can diffuse in two dimensions within the interlamellar spaces leading to appreciable ionic conductivities, described above, and the ability to exchange ions with the surrounding media for use, e.g., in water softening, trapping of toxic metals. Molecules can also be intercalated into the interlamellar spaces leading to applications in catalysis, molecular separation, and properties resulting from oriented molecules, e.g., nonlinear optics (see *Acid Catalysts*, *Acid Catalysts* and *Metal Chain Compounds*). Useful layered phosphates, such as those described below, typically contain high-valence metals such as zirconium, vanadium, or uranium.

α -Zirconium phosphate, $\alpha - \text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, adopts a layered structure in which the hydrogen phosphate groups use three unprotonated oxygens to bond to zirconium while the P–OH groups hydrogen bond to the water molecules in the interlamellar spaces (Clearfield, 1991; Pet'kov, 2012). The layers can adjust their spacing or stacking pattern to adjust to external conditions and any intercalated species. This leads to a diverse chemistry as one or both of the hydrogens can be exchanged by monovalent and divalent cations, and these phases can show various degrees of hydration. Polar molecules such as amines can be reversibly intercalated into $\alpha - \text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$, which can act as an acid catalyst for their reactions. Amine-intercalated $\alpha - \text{Zr}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ and other layered phosphates can be pillared with the Keggin ion $\text{Al}_{13}\text{O}_4(\text{OH})_{12} \cdot \text{H}_2\text{O}^{7+}$ or chromium acetate polymers. Isostructural $\text{M}^{\text{IV}}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$ materials are obtained with $\text{M} = \text{Ti, Hf, Ce, and Sn}$, and analogous layered phosphonates $\text{M}^{\text{IV}}(\text{RPO}_3)_2 \cdot \text{H}_2\text{O}$ contain organic (R) groups between the inorganic layers in place of the OH groups in the hydrogen phosphates. Gamma compound with two chemically distinct types of phosphate group (Clayden, 1987) $\gamma - \text{M}^{\text{IV}}(\text{H}_2\text{PO}_4)(\text{PO}_4) \cdot 2\text{H}_2\text{O}$ are found for $\text{M} = \text{Zr, Ti}$ (Nilchi *et al.*, 2004).

Vanadyl phosphate, α - VOPO_4 , is one of a series of layered oxosalts MOXO_4 ($\text{M}=\text{V}, \text{Nb}, \text{Ta}, \text{Mo}$; $\text{X}=\text{P}, \text{As}, \text{S}$) (Jacobson, 1992). Each vanadyl (VO^{3+}) group is coordinated by four phosphate groups and vice versa. Weak $\text{V}=\text{O}\cdots\text{V}=\text{O}$ interactions hold the layers together, which enables one equivalent of Lewis base molecules to be intercalated through coordination to the vanadyl group. $\text{VOPO}_4\cdot\text{L}$ derivatives are formed with $\text{L}=\text{H}_2\text{O}, \text{ROH}, \text{Py}$, etc. Cross-linked layers are found in $\text{VOPO}_4\cdot(4, 4 - \text{bipyridine})_{1/2}$. Cation insertion reactions occur under mildly reducing conditions giving a variety of $\text{M}_x\text{VOPO}_4\cdot n\text{H}_2\text{O}$ derivatives, e.g., $\text{Na}_{0.2}\text{VOPO}_4\cdot 2\text{H}_2\text{O}$. This results in a decrease in the interlayer spacing due to the electrostatic attraction between the anionic layers and the inserted cations.

Similar uranyl phosphate layers are found in hydrogen uranyl phosphate (HUP), $\text{HUO}_2\text{PO}_4\cdot 4\text{H}_2\text{O}$. The two-dimensional network of hydrogen-bonded water molecules lying between the layers accommodates the extra proton, which gives rise to very high proton conductivities (see Section "Fast Ion Conductors"). HUP and other members of the torbenite group of minerals can undergo cation exchange, e.g., autunite, $\text{Ca}(\text{UO}_2\text{PO}_4)_2\cdot n\text{H}_2\text{O}$, reversibly exchanges Ca^{2+} for K^+ , Ba^{2+} , Mn^{2+} , Cu^{2+} , and Mg^{2+} in aqueous solutions (Pet'kov, 2012).

Microporous Materials

An enormous number of microporous metal phosphates (Yu and Xu, 2003) can be prepared, in which large cavities and channels are enclosed within a strongly bonded $\text{M}-\text{O}-\text{P}$ framework. Such materials can have zeolitic properties, enabling ions and molecules to be adsorbed and react within the pores (see *Acid Catalysts, Organic-Inorganic Composite Crystals, and Zeolites*). Infinite networks of alternating PO_4 and MO_4 tetrahedra analogous to silicate structures are formed with divalent and trivalent M . Aluminophosphates (AlPOs) with $\text{M}=\text{Al}$ are most common (Wilson and Flanigen, 1989) but tetrahedral structures with $\text{M}^{3+}=\text{B}^{3+}$, Ga^{3+} , and Fe^{3+} are also known. $\text{M}^{2+}=\text{Be}^{2+}$, Mg^{2+} , Co^{2+} , and Zn^{2+} give anionic tetrahedral networks. These materials are obtained by a hydrothermal route with organic molecules such as amines or alkylammonium ions as structure-directing agents (SDAs) (Castro et al., 2010; Yu and Xu, 2006). A notable AlPO is the very large-pore material VPI-5 containing one-dimensional channels. The connecting windows have diameters of 12 Å enabling the structure to reversibly sorb large molecules such as $(\text{C}_4\text{F}_9)_3\text{N}$. Further variation of the structural and catalytic properties of AlPOs is obtained by the substitution of aluminum by silicon or metal cations, e.g., magnesium, manganese, iron, cobalt, or zinc. These give the possibility of framework redox activity (e.g., $\text{Fe}^{2+}/\text{Fe}^{3+}$) in catalysis as well as the usual Brønsted acidity.

Oxidation Catalysts

Several transition metal phosphate systems catalyze mild oxidations of organic molecules (Monceaux and Courtine, 1991). Catalysis takes place at particle surfaces through transition metal redox couples. V^{IV} and V^{V} phosphates catalyze the selective oxidation of linear C_4 hydrocarbons to maleic anhydride through the in situ formation of $(\text{VO})_2\text{P}_2\text{O}_7$. The structure of the initial vanadium phosphate is important in determining the morphology and catalytic activity of the $(\text{VO})_2\text{P}_2\text{O}_7$ particles. Highly active, platey microcrystallites can be prepared through the topotactic decomposition of the layered precursor $\text{VOHPO}_4\cdot 1/2\text{H}_2\text{O}$. A similar catalysis of the oxidative dehydrogenation of isobutyric acid to methacrylic acid occurs at the surface of mixed-valent $\text{Fe}^{2+}/\text{Fe}^{3+}$ phosphates.

The NASICON-type phase $\text{CuTi}_2(\text{PO}_4)_3$ catalyzes the oxidation of propylene to acrolein and alcohol dehydrogenations. The open titanium phosphate framework enables copper ions to diffuse to the surface giving surface growths of copper metal or oxides which catalyze the reaction (see *Supported Catalysts*).

Cobalt-Phosphate (Co-Pi) are used for water oxidation Catalyst (Kanan et al., 2008). High surface Co-Pi oxygen evolving catalysts form as thin films on conducting surfaces when aqueous solutions of Co^{2+} salts are electrolyzed in the presence of phosphate. Electrode prepared from Co-Pi achieves a current density of 100 mA cm^{-2} for water oxidation at 442 mV overpotential (Esswein et al., 2011).

Ferroics

Ferroics can be switched between two or more oriented states under appropriate forces. The charge separation present in metal phosphates gives rise to electric dipoles that can result in ferroic properties for which the switching forces are electrical or mechanical (Quarton, 1991). Ferroelectrics possess a net polarization due to parallel ordering of local dipoles; this requires an acentric crystal structure. The members of the potassium dihydrogen phosphate (KDP) family, MH_2PO_4 ($\text{M}=\text{Na}, \text{K}, \text{Rb}, \text{Cs}$), are archetypal ferroelectrics. In KDP the net polarization results from the ordering of asymmetric $\text{P}-\text{O}-\text{H}\cdots\text{O}-\text{P}$ hydrogen bonds below $T_c = 123\text{K}$. Additional $\text{N}-\text{H}\cdots\text{O}-\text{P}$ hydrogen bonding in $\text{NH}_4\text{H}_2\text{PO}_4$ (ADP) gives a slightly different ordering of the acidic protons in which the dipoles cancel out; this is an antiferroelectric phase.

Ferroelectricity also arises in $\text{AM}_2(\text{PO}_4)_3$ types ($\text{A}=\text{Li}-\text{Cs}, \text{Ag}, \text{Cu}$; $\text{M}=\text{Ce}, \text{Th}, \text{U}$) through A cation displacements and in AMPO_4 materials (e.g., $\text{A}=\text{Rb}, \text{Cs}$; $\text{M}=\text{Mg}, \text{Co}, \text{Zn}$) through coupled rotations of the MO_4 and phosphate tetrahedrons. Piezoelectricity, a stress-induced polarization, is found in KDP-type materials and ADP was formerly used in submarine applications to emit and receive ultrasonic waves.

Nonlinear Optical Materials

Materials having a bulk polarization (i.e., ferroelectric phases) may be used for nonlinear optical processes such as second harmonic generation and electro-optic switching (see *Molecular Nonlinear Optical Materials*). KTP, described below, is a very efficient nonlinear material (Hagerman and Poeppelmeier, 1995; Satyanarayan *et al.*, 1999). The KDP materials described in the previous section are inferior to KTP but find use in electro-optics as they are very transparent over a wide frequency range.

The structure of potassium titanyl phosphate, KTiOPO_4 , consists of helical chains of TiO_6 octahedrons interlinked by orthophosphate groups to give a framework containing channels in which K^+ ions reside. The Ti^{4+} ions are displaced away from the centers of the octahedra due to the formation of dipolar $\text{Ti}=\text{O}$ “titanyl” groups, resulting in a net hyperpolarizability. KTP is an efficient second harmonic generator, converting the near-IR emission of Nd-YAG lasers (1064 nm) into blue-green light of twice the frequency (532 nm). It may also be used for optical frequency mixing, in electro-optic modulation devices and optical waveguides. Good-quality single crystals of KTP are grown from $\text{K}_2\text{O}-\text{P}_2\text{O}_5$ fluxes or hydrothermally. Cation-exchanged ATiOPO_4 derivatives ($\text{A}=\text{Ag}, \text{Na}, \text{Rb}, \text{Cs}, \text{Tl}, \text{NH}_4$) have been prepared to modify the nonlinear properties.

Phosphors and Laser Materials

These both require a non-absorbing host containing a low concentration of optically active centers. Phosphors contain absorption and emission centers; fluoroapatite, $\text{Ca}_5(\text{PO}_4)_3\text{F}$, doped with antimony and manganese is very efficient and is used as a coating in fluorescent lamps to convert 254 nm mercury UV radiation into visible light. $\text{Na}_3(\text{Ce}_{0.65}\text{Tb}_{0.35})(\text{PO}_4)_2$ and lanthanide-doped $\text{Zn}_3(\text{PO}_4)_2$ are also efficient phosphors. Polyphosphate glasses such as NaPO_3 or $\text{Al}(\text{PO}_3)_3$ containing < 1% neodymium dopant are used in high-gain or high-power laser applications (Campbell and Suratwala, 2000; Marion and Weber, 1991); other lanthanide like Europium are studied (Babu *et al.*, 2007). $\text{NdP}_5\text{O}_{14}$ and other lanthanide ultraphosphates have been extensively researched as laser materials. The large cation-cation separations in these lattices enable stoichiometric $\text{NdP}_5\text{O}_{14}$ to lase without excessive fluorescence quenching. Other neodymium phosphate laser crystals are the cyclotetraphosphates $\text{MNdP}_4\text{O}_{12}$ ($\text{M}=\text{Li}, \text{Na}, \text{K}$) and the orthophosphates $\text{M}_3\text{Nd}(\text{PO}_4)_2$ ($\text{M}=\text{Na}, \text{K}$).

Negative Thermal Expansion Ceramics

There has been much recent interest in materials showing negative thermal expansion. They are generally neutral frameworks made up of rigid metal and oxoanion (here phosphate) polyhedra. Heating these materials excites the transverse (bending) $\text{M}-\text{O}-\text{P}$ vibrations with little expansion of the $\text{M}-\text{O}$ and $\text{P}-\text{O}$ bonds. Hence the $\text{M}-\text{P}$ distance decreases with rising temperature, leading to an overall negative expansion in several materials. Zero thermal expansion composites are made by combining these phases with normal (positive) expansion materials. Examples of phosphates showing negative thermal expansion are the diphosphate-divanadate solid solutions $\text{ZrP}_{2-x}\text{V}_x\text{O}_7$ and the microporous aluminophosphate AlPO-17 which shows a particularly large effect (Attfield and Sleight, 1998). Zirconium tungsten phosphate $\text{Zr}_2(\text{WO}_4)(\text{PO}_4)_2$ (ZWP) exhibits the property of NTE of approximately $-5 \times 10^{-6} \text{ K}^{-1}$ from room temperature to 1073K (Watanabe *et al.*, 2008). Some phases $\text{A}_{5-qx}\text{M}_x\text{Zr}(\text{PO}_4)_3$ (N is the 4-, 3-, 2- valent element; $q = 4, 3, \text{ or } 2$; and $5 - qx \geq 1$) which are member of the $\text{NaZr}_2(\text{PO}_4)_3$ (NZP) family of materials have a near-zero net thermal anisotropy (Orlova *et al.*, 2002).

Minerals

Several hundred phosphate minerals are known, virtually all of which are orthophosphates. The important mineral apatite, ideally $\text{Ca}_5(\text{PO}_4)_3\text{X}$ ($\text{X}=\text{F}, \text{Cl}, \text{OH}$), is found in igneous pegmatite rocks and hydrothermal veins. Poorly crystalline or amorphous phosphorite sediments made from the hard remains of marine organisms are the principal commercial source of phosphates, although apatites are also mined. Treatment of phosphate minerals with sulfuric acid yields “superphosphate” fertilizer and phosphoric acid treatment gives “triple superphosphate”, rich in $\text{Ca}(\text{H}_2\text{PO}_4)_2$. Other soluble fertilizers such as ammonium phosphates are obtained from these products. Many of the f-block elements are extracted from phosphate minerals, notably monazite. Torbenite minerals related to HUP (see Section “Intercalation Hosts and Ion Exchangers”) are sources of uranium.

Biomaterials

Phosphates are found in soft organic tissues as phosphate esters, and in hard tissues, notably bones and teeth, which are composites of an organic matrix and biomineralized apatites (Videau and Dupuis, 1991). These apatite phases have Ca/P ratios of 1.6–1.8 and often incorporate other cations (Na^+ , K^+ , Mg^{2+}) or anions (F^- , Cl^- , CO_3^{2-} , citrate). A variety of synthetic calcium phosphates have been investigated as biomaterials for implants (de Groot, 1993; Rey *et al.*, 2017). $\text{Ca}_3(\text{PO}_4)_2$ (TCP) and a mixture of TCP and Hydroxyapatite named biphasic calcium phosphate (BCP) can be used as a biodegradable bone substitute which is gradually replaced by autogenous bone (de Grado *et al.*, 2018). Less degradable apatite implants can attach to natural bone with less inflammation. Calcium phosphate cement are powder mixture of tetracalcium phosphate (TTCP) or dicalcium phosphate anhydrous (DCPA) or dihydrated (DCPD) or TCP or other phases which react in the presence of water (Kenny and Buggy, 2003).

Hydroxyapatite is coated on metallic osteoarticular implant by plasma spray in order to increase the osteointegration (Sun *et al.*, 2001). Bioinert zinc phosphate cements are used in prosthetic dental applications (Herschke *et al.*, 2006).

Summary

An enormous number of solid phosphate materials can be found or synthesized and many still wait to be discovered. They are generally durable, nontoxic, and have a wide range of actual and potential materials applications. Future developments may include new microporous catalysts, structural materials such as zero expansion ceramics, and improved biomaterials.

Apatitic and Tricalcic Calcium Phosphate-Based Bioceramics: Overview and Perspectives

Christophe Drouet and Christèle Combes, CIRIMAT, Université de Toulouse, CNRS/INP/UPS, ENSIACET, Toulouse, France

© 2021 Elsevier Inc. All rights reserved.

Introduction

Calcium phosphates represent a major class of biominerals found in a variety of living organisms, and strategies are developed to prepare synthetic analogs for biomedical applications such as bone regeneration but also in other (nano)medicine domains as for cell therapy. While nanocrystalline, non-stoichiometric apatites mimic bone mineral and dentin, and exhibit a high (surface) bioactivity, stoichiometric hydroxyapatite (HA) is thermally/thermodynamically very stable and approaches more the composition of tooth enamel. Besides apatitic compounds, other calcium phosphate (CaP) phases are also particularly relevant to biomedical applications such as bone repair, like tricalcium phosphates (TCPs, especially the high temperature α and β forms or the low temperature forms, amorphous TCP and apatitic TCP). These various compounds, apatitic and tricalcic, are the most used CaP phases to-date in the biomedical field, and may offer a large panel of bioceramic-based systems with diverse characteristics (mechanical, biological, chemical, thermodynamic...) so as to comply with clinical needs. One main applicative domain is certainly the production of resorbable or non-resorbable bone implants, which may also associate drugs and other active agents. In this chapter, an overview will be given on both apatitic and tricalcic CaP compounds, in terms of structure, synthesis and processing routes, physicochemical characterization and main biological properties. Biphasic systems such as HA/ β -TCP, also known as biphasic calcium phosphate (BCP) bioceramics, will also be addressed. Finally, some conclusive remarks and perspectives are given.

Apatitic Ceramics

Overview

Apatites are a large group of minerals sharing a similar crystallography and responding to the general formula $M_{10}(XO_4)_6Y_2$ (Elliott, 1994). For biomedical applications, however, the metallic cations M mostly represent calcium – although a wealth of substitutions may occur – and XO_4 mainly stands for phosphate groups. In this context, the reference apatitic compound is stoichiometric hydroxyapatite $Ca_{10}(PO_4)_6(OH)_2$, denoted HA. This compound is not naturally encountered in vivo, except that tooth enamel exhibits a mineral composition that approaches it despite some carbonation and a few residual ion vacancies. HA is however one key ceramic compound for the setup of bone substitutes and is widely used at a clinical scale, especially when non-resorbable scaffolds are needed. In bone, dentin and synthetic biomimetic analogs obtained by soft chemistry (typically temperature lower than 100°C and in the absence of high-temperature calcination), in contrast, the apatitic phase is clearly non-stoichiometric with vacancies in Ca^{2+} and OH^- sites, and part of the PO_4^{3-} ions are also protonated as HPO_4^{2-} divalent anions and substituted by carbonate ions (B-type). A-type carbonate ions can also be present in substitution of some OH^- ions, although to a limited amount (Gomez-Morales *et al.*, 2013). This non-stoichiometry confers a thermodynamic metastability (Rollin-Martinet *et al.*, 2013), but also an associated greater reactivity/bioactivity. Reviews of apatitic compounds have been reported (Combes *et al.*, 2016; Dorozhkin, 2009; Gomez-Morales *et al.*, 2013; LeGeros, 1991, 2008; Sakae *et al.*, 2015). A general chemical formula can be written to approximate the global composition of these compounds: $Ca_{10-x}(PO_4)_6-x(HPO_4, CO_3)_x(OH)_{2-x}$. This overall formula points to a Ca/P (+ C) molar ratio lower than the stoichiometric value of 1.67; however it does not depict in detail the complex sub-structure of biological and biomimetic nanocrystalline apatites which exhibit, on the surface of their nanocrystals, a hydrated ionic layer which is non-apatitic (ion organization within this layer does not correspond to the apatite array) (see below). This layer has a low Ca/P (+ C) ratio, potentially close to 1, and contains labile ions that can be easily exchanged with ions from the surrounding fluids and take an active part in molecular adsorption processes (Cazalbou *et al.*, 2005; Eichert *et al.*, 2005; Rey *et al.*, 2014). The high reactivity of these compounds can then be modulated thanks to appropriate associations with ions and (bio) molecules to offer additional functionalities to the derived bioceramics, thus opening a large variety of medical applications in the field of bone regeneration, but also in (nano)medicine.

Structure

Apatite compounds – and in particular calcium phosphate ones – generally crystallize in the hexagonal $P6_3/m$ space group (sometimes monoclinic $P2_1/b$ as in the case of chlorapatite for example) (Elliott, 1994). Hydroxyapatite, for instance, exhibits typical unit cell parameters close to $a = 9.418 \text{ \AA}$ and $c = 6.881 \text{ \AA}$, leading to a theoretical density of about 3.16 (Kay *et al.*, 1964; Rey *et al.*, 2011). The 3D organization of the atoms in the unit cell is based on a compact-like arrangement of phosphate groups and some interstitial sites are occupied by calcium and hydroxide ions. This organization generates two types of so-called channels, often denoted Ca(1) and Ca(2) in relation to the location of the calcium atoms. In particular, the axis of the

Fig. 1 Representation of part of the hydroxyapatite structure: Ca(2) apatitic channels along the c-axis, hosting the OH⁻ ions. From Elliott, J.C., 1994. *Structure and Chemistry of the Apatites and other Calcium Orthophosphates*. Amsterdam: Elsevier Science.

Ca(2) channels (Fig. 1) can accommodate a variety of anions (e.g., OH⁻, Cl⁻, F⁻, A-type CO₃²⁻, peroxides...) but also small molecules (e.g., glycine), and these confined species can take part in exchange reactions as in chromatography setups although specific conditions need to apply for such exchanges to take place.

The 3D cohesion of the apatite ionic crystal is maintained by strong electrostatic interactions between the cations and anions attracting each other. The phosphate ions are large entities that convey stability to the structure, therefore vacancies in phosphate site have not been reported; only substitutions by other ions such as carbonates CO₃²⁻ (B-type carbonates) or other large ions can be undergone in phosphate sites. Nonstoichiometry can thus solely be linked to vacancies in cationic sites (replacement of Ca²⁺) and in monovalent anionic sites (replacement of OH⁻). The clear impact of Ca/OH vacancies on the stability of the crystal was evaluated on the basis of calorimetry experiments (Rollin-Martinet *et al.*, 2013). These ions can also be substituted by a wealth of others. Common cationic substituents can be bioactive ions such as Mg²⁺, Sr²⁺, Cu²⁺, Zn²⁺, among others, or inert like Na⁺, but also toxic ones like Pb²⁺ or Cd²⁺. Again, these ions being potentially different in size, charge, affinity for oxygen, etc., their substitution in the apatitic lattice will generate modifications in their thermodynamic properties (Drouet, 2015).

Synthesis and Processing Routes

Two situations should be differentiated (Drouet *et al.*, 2017), whether well-crystallized or nanocrystalline apatites are considered, as this will dictate the synthesis and processing route to carry out.

Well-crystallized apatites

Well-crystallized apatites, such as stoichiometric HA, may only be obtained upon heating, e.g., close to water boiling temperature, and this is often accompanied by a thermal post-treatment in dry conditions for improving its crystallinity and/or densification rate. Sintering indeed allows increasing drastically the mechanical strength of obtained bioceramics or at least precursor forms (e.g., granules) (Khalil *et al.*, 2007; Kobayashi *et al.*, 2006; Raynaud *et al.*, 2002). Stoichiometric HA remains stable up to typically ~1250°C without major alteration, unless very low water pressure conditions are used, leading to partial dehydration from 850°C generating oxyapatite (Trombe and Montel, 1978).

Such well-crystallized apatite can be typically prepared by neutralization, in stoichiometric amounts, of phosphoric acid by calcium hydroxide (lime) or another calcium source such as calcium nitrate (where the nitrates will be subsequently eliminated upon washing and calcination). When using lime as precursor, however, attention should be paid as this compound has a strong

tendency to partially dehydrate in variable proportions, thus making arduous the stoichiometric assessment of the number of moles of calcium. One solution is to pre-calcine (e.g., at 600°C) the lime prior to synthesis and weigh the desired amount after cooling down to room temperature in a desiccator. Then, any post-rehydration is inconsequential on the synthesis outcome. Other phosphate precursors can also be used, such as di-ammonium hydrogenphosphate. In any case, fixing the pH to alkaline conditions, e.g., pH 10 via ammonia addition, will facilitate the obtainment of stoichiometric HA. Solid state reactions can also be used to prepare HA, e.g., 1000°C (Suchanek and Yoshimura, 1998), starting from a phosphate and a calcium precursor such as calcium carbonate.

The stoichiometry of prepared HA, for which a Ca/P ratio of 1.67 is expected (within experimental uncertainty) may be verified by calcination for 15 h at 1000°C (ISO 13779-3:2008), via X-ray diffraction (XRD) analysis where only the HA phase should be detected. The presence of β -TCP besides the HA phase would depict a situation where under-stoichiometric apatite $\text{Ca}_{10-x}(\text{PO}_4)_{6-x}(\text{HPO}_4)_x(\text{OH})_{2-x}$ is obtained, with a Ca/P ratio between 1.50 and 1.67. Note that for even lower Ca/P ratios (< 1.50) calcination would lead to a mixture of β -TCP and calcium pyrophosphate $\text{Ca}_2\text{P}_2\text{O}_7$. The residual presence of CaO, after 15 h of calcination at 1000°C, detected by XRD would indicate in contrast that calcium was initially present beyond the stoichiometric amount. Traces of CaO can also be assessed by a pink coloration upon contact with a phenolphthalein solution. The residual CaO can however be eliminated by a washing procedure.

Well-crystallized, stoichiometric HA can be processed in different forms in view of bioceramic usages, and especially as bone substitutes such as dense or porous scaffolds, granules, coatings on metal prostheses... In porous structures (Meurice *et al.*, 2012; Sopyan *et al.*, 2007), macropore interconnection (typically in the range 300–500 μm) are bound to allow cell colonization and favor osteointegration (Karageorgiou and Kaplan, 2005; Lu *et al.*, 1999; Mastrogiacomo *et al.*, 2006). Such pores can be obtained via pore-forming agents (e.g., NaCl, CaCO_3 , glucose, paraffin...) that will be either washed away or eliminated by calcination during a subsequent heating process (Chevalier *et al.*, 2008; Descamps *et al.*, 2009; Tancrét *et al.*, 2006; Walsh and Tanaka, 2001). Other approaches such as stereolithography, freeze casting or else the transformation of naturally-porous biological calcium carbonates into calcium phosphate can be used (Charrière *et al.*, 2003; Gonzalez-McQuire *et al.*, 2005; Liu, 1997; Meurice *et al.*, 2012; Walsh *et al.*, 2005).

HA is also widely used in the field of implant coatings. Today and since the mid-1980s, HA is indeed used, from a commercial viewpoint, as starting precursor to feed plasma spray guns to deposit hydroxyapatite (although partially decomposed) onto prosthetic devices such as hip implants (Sun *et al.*, 2001) in order to favor their osteointegration (Buser *et al.*, 1991; Jarcho, 1986).

Nanocrystalline apatites

The preparation of bone-like nanocrystalline, non-stoichiometric apatites (also called biomimetic when prepared close to physiological conditions) can only be carried out at low temperature, in solution. This can typically be done by double decomposition of a calcium and a phosphate precursor, or by hydrolysis of an unstable CaP compound (Gomez-Morales *et al.*, 2013; Markovic *et al.*, 2011). In these conditions, the obtained apatite compounds (provided that they are not heated too high due to their metastability) exhibit very similar features to bone apatite. Synthesis of carbonated or non-carbonated biomimetic nanocrystalline apatites can thus be done this way (Grunenwald *et al.*, 2014b; LeGeros, 1994; Vandecastelaere *et al.*, 2012). For carbonation, a carbonate-containing precursor such as NaHCO_3 has to be added in the phosphate precursor medium.

Suspensions or “gels” of nanocrystalline apatites are obtained upon filtration (and washing) of the precipitating medium, and their drying leads to ceramic pieces, although characterized by limited mechanical strength (Sarda *et al.*, 1999). Bone-like apatite can also be the final product after the setting of calcium phosphate cements, whether the latter is based on the hydrolysis of a precursor CaP phase e.g., α -TCP (Ginebra, 1997) or on acid-base reaction (Constantz, 1995). Calcium carbonate may also be associated to CaP-based cement formulations (Combes *et al.*, 2006) to obtain carbonated nanocrystalline apatite biomimetic cements and/or modulate their resorption in vivo.

It is also possible to prepare 3D scaffolds via a consolidation step. However, again, low/moderate temperatures need to be applied so as to prevent the degradation of the metastable nanocrystals and their bone-like features such as hydration and nanosized dimensions. Flash sintering such as spark plasma sintering (SPS) carried out at low temperature (e.g., 150°C) has been proved to be an effective way to consolidate nanocrystalline apatites while preserving these appealing nanocrystals characteristics (Drouet *et al.*, 2006; Grossin *et al.*, 2010; Ortali *et al.*, 2018). These cold sintering approaches revealed that it was possible to use the intrinsic water contained in the samples (within the hydrated surface layer) to consolidate apatite nanocrystals, via the merging of the surface layers of adjacent nanocrystals. The role of the hydrated layer in assisting the sintering of iodate-containing HA crystals was also shown (Coulon *et al.*, 2016). A similar type of “cold fusion” is probably likewise involved in the case of enamel formation (Daculsi *et al.*, 1984). Mechanical properties after SPS consolidation become attractive for non-load-bearing sites in orthopedics and dentistry, e.g., with a Young modulus in the range 12–37 GPa, close to cortical bone (7–30 GPa). Mineral-organic composites involving nanocrystalline apatite can also be prepared, where a polymer can typically modulate mechanical properties and/or allow the formation of (macro)porous scaffolds, whether obtained by SPS (Brouillet *et al.*, 2015) or via other methods such as freeze-casting (Schardosim *et al.*, 2017).

Nanocrystalline apatite coatings on implants can be obtained by soft chemistry routes such as electrodeposition or dip-coating in apatite suspensions (Abe *et al.*, 1990; Autefage *et al.*, 2009; Blackwood and Seah, 2009; Chai and Ben-Nissan, 1999), and results pointed to the osteoinductive character of such biomimetic apatite (Autefage, 2009). More recently, cold spray was shown as another low temperature processing approach for the realization of nanocrystalline apatite coatings (Kergourlay *et al.*, 2016), while preserving the appealing characteristics of the initial nanocrystals.

Finally, the nanometer scale of bio-inspired apatites allows for the preparation of individualized apatite nanoparticles relevant to cell therapy/(nano)medicine (Drouet *et al.*, 2015; Iafisco *et al.*, 2012; Welzel *et al.*, 2004), and applications in the fields of oncology, hematology, dermatology, transfection and medical imaging (typically via lanthanide substitution in the apatite lattice (Al-Kattan *et al.*, 2010; Mondéjar *et al.*, 2007)) are being developed.

In all cases, whether in the form of gels/pastes, coatings, particles or scaffolds, the high reactivity of apatite nanocrystals makes it possible to convey additional functions such as antibacterial, antitumor, luminescence etc., via ion substitutions/exchanges or molecular adsorption/grafting (biomolecules, drugs...).

Physicochemical Characterization

Various complementary techniques can be used to characterize CaP compounds such as apatites, and also permit to distinguish between bone-like apatites and well-crystallized, stoichiometric HA (Drouet, 2013). While X-ray diffraction allows getting information on the crystalline features of HA or the apatitic core of biomimetic apatites, for example to estimate the mean crystallite dimensions, it does not convey direct information on the non-apatitic disordered layer from the nanocrystals surface which has an amorphous-like character (although some degree of organization exists as seen by vibrational spectroscopy). Electron microscopy such as (HR)TEM or (FEG)SEM have also to be used with caution, unless in cryogenic conditions (Drouet *et al.*, 2018a), as crystal damage can be provoked upon beam (and high vacuum) exposure (Bres *et al.*, 2014).

In contrast, vibrational spectroscopy techniques (FTIR, Raman) appear very well suited to analyze apatitic compounds, and they allow exploring the local chemical environment of ions within the structure. Very specific features (Fig. 2) have for example been reported to exist in bone apatite or in biomimetic synthetic counterparts, e.g., by FTIR spectroscopy (Boskey and Mendelsohn, 2005; Drouet *et al.*, 2018b; Miller *et al.*, 2001; Paschalis *et al.*, 2011; Rey *et al.*, 1989a,b, 1991a,b,c, 1990) which do not appear in stoichiometric HA. Some relationship with the IR spectrum of octacalcium phosphate (OCP) $\text{Ca}_8(\text{PO}_4)_6(\text{HPO}_4)_2 \cdot 5\text{H}_2\text{O}$ can also be unveiled (Fowler *et al.*, 1993). These features permit to evidence the presence or absence of a hydrated non-apatitic layer on the nanocrystals. The signature of non-apatitic (surface) HPO_4^{2-} ions around 534 cm^{-1} is one such signature. Also, the degree of hydroxylation can be scrutinized by looking at the OH libration band at 632 cm^{-1} . A lower OH⁻ signal and the presence of HPO_4^{2-} ions is then a clear evidence of the non-stoichiometry of the sample. Raman spectroscopy can also be used to detect non-apatitic signatures on apatite nanocrystals (Crane *et al.*, 2006). In microscopy setup, Raman spectroscopy also allows drawing mappings and may be used directly in aqueous media (e.g., in cell culture medium). FTIR (and Raman) spectroscopies also allow distinguishing apatitic compounds from other CaP phases such as dicalcium phosphate dihydrate ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$, DCPD) or OCP, or even amorphous CaP which leads to large, nearly monocomponent bands in the ν_3 and $\nu_4(\text{PO}_4)$ domains. A review on vibrational spectroscopy features of CaP compounds has been recently published (Rey *et al.*, 2014c). Another spectroscopy technique particularly informative for CaP compounds including apatites is solid state nuclear magnetic resonance (NMR), especially regarding the elements P, H, C, Ca and F (Arends *et al.*, 1987; Beshah *et al.*, 1990; Laurencin *et al.*, 2010; Roufosse *et al.*, 1984; Yesinowski, 1998; Yi *et al.*, 2013). This technique allowed confirming results obtained by other methods such as vibrational spectroscopies, regarding the existence of a disordered CaP hydrated layer on the surface of bone apatite nanocrystals or their biomimetic counterparts (Sfihi and Rey, 2002; Jäger *et al.*, 2006; Von Euw *et al.*, 2017, 2019; Wu *et al.*, 2002).

Chemical analyses are also key for a thorough characterization of such samples. Cationic contents can be measured by ICP or atomic absorption spectrometry, or else complexometry (e.g., with EDTA) although the latter is not specific to a given type of cation. Methods based on particle beams such as particle-induced X-ray emission (PIXE) can also be employed (Jallot and Moretto, 2006; Loong *et al.*, 2000), e.g., to obtain element mappings, but they request the use of heavy equipment. Phosphates can be titrated by UV-visible spectrophotometry of a phospho-vanado-molybdenic complex (Charlot, 1974). The carbonation level can be chemically assessed from coulometry (Huffman, 1977) or directly from FTIR spectrometry analyses (Grunenwald *et al.*, 2014a).

Surface analysis techniques can also be used to complement the physicochemical characterization, such as atomic force microscopy (AFM) (McElderry *et al.*, 2013; Onuma *et al.*, 1995; Robinson *et al.*, 2005; Ramirez Rodriguez *et al.*, 2016), X-ray photoelectron spectroscopy (XPS) (Lu *et al.*, 2000; Takadama *et al.*, 2001) or electron paramagnetic resonance (EPR) (Fattibene and Callens, 2010).

Biological Properties

The biological response of implanted materials (typically in terms of bioactivity, tissue integration, degradation...) is directly linked to their physicochemical features.

Due to its high stability, stoichiometric HA is the most stable CaP compound in physiological conditions (Brown and Kornberg, 2004). As such, it is characterized by a low solubility *in vivo* leading to a slow bioresorption: it may be considered as "non bioresorbable" and adhered osteoclasts were reported to have difficulties to spread and form resorption pits (Redey *et al.*, 1999). In contrast, biomimetic nanocrystalline apatites are expected to resorb significantly faster due to their lower thermodynamic stability (Rollin-Martinet *et al.*, 2013) leading to a higher solubility. Upon maturation however, their dissolution by osteoclasts was reported (Kim *et al.*, 2001) to decrease *in vitro* as the amount of labile (hydrogen)phosphate decreases on the apatite nanocrystals: the more mature the nanocrystals, the less resorbable.

a) $\nu_4\text{PO}_4$ domain

b) $\nu_3\text{PO}_4$ domain

Fig. 2 Example of IR spectral decompositions (non-carbonated biomimetic apatite matured 1 day): (a) In the $\nu_4\text{PO}_4$ domain: the central zone corresponding to the 574 cm^{-1} band contains most probably an important contribution of non-apatitic (n.a) species. The best defined peaks and the thinnest ones can be attributed to apatitic (a) phosphates by reference to well-crystallized apatites. The non-apatitic phosphates (PO₄ and HPO₄), leading to wider bands, are only apparent on the sides of the envelope, where peaks attributed to apatitic phosphates have a relatively low intensity. (b) In the $\nu_3\text{PO}_4$ domain: attributions are based on those of Fowler for OCP and those proposed by Paschalis *et al.* Although the $\nu_3\text{PO}_4$ bands are the most intense from phosphate ions in IR spectroscopy, the various components are here significantly less well resolved than in the $\nu_4\text{PO}_4$ domain. The decomposition is not unique and remains more difficult to assess; moreover, no correspondence has been quantitatively established so far. Despite their relevance to the clinic, to date only a limited amount of *in vivo* data is available on nanocrystalline apatite systems for which the development has occurred more recently. While HA is bioactive but “only” osteoconductive, the additional osteoinductivity of apatite nanocrystals deposited as a coating on BCP granules was nonetheless demonstrated intramuscularly in

Fig. 3 Example of HA/collagen composite implantation data: optical microphotograph of H-E stained cross section at 12 weeks after implantation in beagle's tibia. Osteoclastic cells (multinucleated giant cells) resorbed the composite and created Howship's-like lacunae and osteoblasts formed new bone at surrounding of the composite. From Kikuchi, M., Ikoma, T., Itoh, S., *et al.*, 2004a. Biomimetic synthesis of bone-like nanocomposites using the selforganization mechanism of hydroxyapatite and collagen. *Composites Science and Technology* 64, 819–825.

the sheep, and the study also showed that an almost doubled amount of BMP-2 growth factor could be associated to the coated granules for accelerating bone regrowth (Autefage, 2009; Autefage *et al.*, 2009). Coatings of stoichiometric HA obtained by plasma spray are, on the other hand, commercially and clinically available (let us however remind that part of the HA phase has decomposed and only partially recomposed into HA in the torch), and although non osteoinductive, they were shown to allow improved osteointegration (De Groot *et al.*, 1987).

In vitro, the behavior of (rat) osteoblasts and (human) mesenchymal stem cells (MSC) was scrutinized and compared between sintered and biomimetic CaP (Sadowska *et al.*, 2017). Both types of cells were found to be sensitive to the ionic modifications undergone in the culture medium upon immersion of bone-like apatite, leading to a decrease in proliferation rate compared to sintered HA, especially of MSC. Higher alkaline phosphatase (ALP) activity for both cell types was also noticed for biomimetic apatite, pointing to a promotion of the osteoblast phenotype. The inflammatory response of HA particles with different morphologies was also investigated *in vitro* (using primary human polymorphonuclear cells (PMNCs), mononuclear cells (MNCs), and human dermal fibroblasts (hDFs)) or *in vivo* (subcutaneously in mice) (Pujari-Palmer *et al.*, 2016). A 2-fold decrease in viability was observed after exposure to HA particles of fiber morphology on PMNCs and hDFs, while MNC viability decreased 5-fold after treatment with dot-like particles. Also, a greater level of reactive oxygen species (ROS) was reached with the fibers in both PMNCs and MNCs, and the highest degree of apoptosis on all these cell types. Moreover, greater capsule thickness was noted subcutaneously in mice after exposure to fibers and dots morphologies.

In the form of self-supported scaffolds, apatitic systems were shown to exhibit bone regeneration ability, and bone-like apatite was again shown to have superior properties. For example, Mg-doped and MgCO_3 – cosubstituted materials were found to enhance MSC and osteoblast-like cells (MG63) in terms of adhesion, proliferation and metabolic activation compared to stoichiometric HA (Landi *et al.*, 2006). Ionic doping can also provide specific features. The effect of several inorganic substituents has been reviewed (Yang *et al.*, 2010). For example, Ag-doped apatites were shown to exhibit antibacterial and antifungal properties (Ciobanu *et al.*, 2013). Moreover, MG63 osteoblast-like cells cultivated on bone-like doped apatites showed that the presence of Mg^{2+} and Sr^{2+} promoted proliferation and expression of collagen I, and that the presence of Mn^{2+} ions had a noticeable positive effect on osteocalcin production (Bracci *et al.*, 2009).

Porosity is another factor with a direct effect on bone regrowth: porous HA scaffolds with micro-channels (25–30 μm) have been for example implanted in dogs, unveiling an increase in bone density compared to non-porous HA (Ren *et al.*, 2018). *In vitro*, a significant promotion of human placenta-derived mesenchymal stem cell (hPMSC) on osteogenic differentiation and maturation of osteoblasts was also pointed out by the authors for these porous HA scaffolds. This effect is postulated as being related to larger protein adsorption capabilities as well as promoting facilitated expression of osteogenic genes. Microporosity modulates the particle surface topography and this was reported to be impactful on cell proliferation and ALP activity (Rosa *et al.*, 2002).

As mentioned previously, combinations are also possible with organic components such as (bio)polymers, and this strategy may allow approaching even further the natural composition and/or architecture of bone while providing adequate conditions for bone repair (Itoh *et al.*, 2000; Kikuchi *et al.*, 2004a; Kim *et al.*, 2005; Tampieri *et al.*, 2003, 2011). Facilitated formation of bony tissue was reported, for example in view of osteochondral use (Itoh *et al.*, 2002; Kon *et al.*, 2010), and its resorption/neof ormation upon bone cell activity can be followed (Fig. 3). At a cellular level, the presence of polymers such as chitosan may improve cell proliferation (Kong *et al.*, 2005). The *in vivo* resorption rate of the organic component should however be selected carefully so as to avoid a too high foreign-body reaction and allow time for new bone tissue formation/apposition (Rovira *et al.*, 1993).

Mini-invasive surgery can be obtained using cement formulations (Burguera *et al.*, 2006; Knaack, 1998), and bone-like apatite can be the final product after cement setting. Advantages over more massive pieces are also their possible injectability and easier and better filling of bone defects with complex geometries. Their biocompatibility and bone repair abilities have been well documented (Bohner, 2010; Laschke *et al.*, 2007; Theiss *et al.*, 2005; von Rechenberg *et al.*, 2013).

Beyond bone applications, apatite (nano)particles can also be used in “(nano)medicine” for cell or tissue therapy (Drouet *et al.*, 2015; Iafisco *et al.*, 2012; Stefanic *et al.*, 2017; Welzel *et al.*, 2004), in particular due to their mimicry to bone apatite leading to highly biocompatible systems. Application fields may be wide and are in the process of being investigated. This is all the more relevant that ionic substitutions and/or molecular adsorptions can lead to tailored nanosystems with additional functionalities relevant to the targeted uses. Examples of applications are transfection, intracellular drug delivery in the fields on oncology (Adamiano *et al.*, 2018; Epple *et al.*, 2010; Iafisco *et al.*, 2016; Meshkini and Oveisi, 2017; Sarda *et al.*, 2018), hematology (Stefanic *et al.*, 2017), medical imaging (Al-Kattan *et al.*, 2010, 2014; Altinoglu *et al.*, 2008; Doat *et al.*, 2003; Guo *et al.*, 2008; Gómez-Morales *et al.*, 2018; Mondéjar *et al.*, 2007; Morgan *et al.*, 2008). The requirement of individualized circulating nanoparticles faces the question of the control of agglomeration, which is usually obtained via an organic corona adsorbed around the nanoparticles. Keeping in mind the biomedical requirements, only biocompatible organic agents can be selected to form this corona. Some phosphate/phosphonate compounds have for example been proposed with 2-aminoethyl phosphate (AEP) or phosphonated polyethyleneglycol (PEGp) (Al-Kattan *et al.*, 2010; Bouladjine *et al.*, 2009; Drouet *et al.*, 2015) as well as DNA (Mondéjar *et al.*, 2007; Welzel *et al.*, 2004), and other organics like citrates (Delgado-Lopez *et al.*, 2012; Gómez-Morales *et al.*, 2018). Among associations with active (bio)molecules/drugs, various studies have already been reported involving for instance cell-targeting agents like antibodies (Iafisco *et al.*, 2012) or folic acid (Drouet *et al.*, 2015; Sarda *et al.*, 2018), or else chemotherapeutic drugs like doxorubicin (Iafisco *et al.*, 2016) or methotrexate (Sarda *et al.*, 2018), potentially added in these latter studies to super-paramagnetic properties via Fe doping. Internalization in cells appears to happen via endocytosis, and the acidic conditions (pH 4–5) existing in endo(lyso)somes are thus bound to allow the progressive dissolution of apatite and consecutive drug release, which is associated to the release of natural metabolites such as calcium and phosphate ions.

Tricalcium Phosphate-Based Ceramics

Overview

Since the first trials of implantation of tricalcium phosphate (TCP: $\text{Ca}_3(\text{PO}_4)_2$) compounds, as a suspension, in animals (Albee, 1920), tricalcium phosphate beta (β -TCP) has become one of the first calcium phosphate phases to be used as bioceramics for bone substitution and repair due to its stability at high temperature and easiness of processing as ceramics (Jarcho *et al.*, 1979; Metsger *et al.*, 1982; Nery *et al.*, 1975). β -TCP-based ceramics have been commercialized for a long time and they are one of the major bioresorbable synthetic bone substitutes in use in today's practice of orthopedic and maxillofacial surgeons for the reconstruction of all kinds of bone defects (augmentation of alveolar ridge defects, sinus reconstruction and bone reconstruction following injuries or diseases (Horch *et al.*, 2006; Le Huec *et al.*, 1997; Nakagawa *et al.*, 2006; Ogoose *et al.*, 2005; Szabo *et al.*, 2005)). Today, several TCP phases are used as bioceramics (Table 1): the β -TCP phase which is the most widely used TCP compound, the metastable high-temperature phase α -TCP but also the amorphous tricalcium phosphate (*am*-TCP) and the apatitic tricalcium phosphate (*ap*-TCP); *am*-TCP and *ap*-TCP playing both an important role in coatings on metallic prosthesis and in calcium phosphate cements (Combes and Rey, 2010). TCPs are involved in many bone substitute materials in the form of dense or porous ceramics, coatings on metallic prosthesis, cements and composites.

Structures

Am-TCP has been shown to exhibit a local order studied in detail by Posner *et al.* (Betts and Posner, 1974a,b; Posner and Beebe, 1975). They proposed a model based on the agglomeration of cluster units of 9.5 Å of diameter and with a $\text{Ca}_9(\text{PO}_4)_6$ chemical

Table 1 TCP phases involved in several forms of bioceramics and their related properties

TCP phases	Chemical formula	Forms of bone substitute materials	Main TCP properties involved
α -TCP	$\alpha\text{-Ca}_3(\text{PO}_4)_2$	Cements, Coatings, composites	Dissolution & hydrolysis of α -TCP, <i>ap</i> -TCP and <i>am</i> -TCP; Bioresorbability; Reactivity/provider of Ca^{2+} and PO_4^{3-}
β -TCP	$\beta\text{-Ca}_3(\text{PO}_4)_2$	Ceramics, cements, coatings, composites, scaffolds for tissue engineering	ions (cement setting reaction); Release of ions with biological activity; Mechanical properties (composites)
<i>ap</i> -TCP (Ca-deficient apatite with equal amount of HPO_4^{2-} and OH^- : Ca/P = 1.5)	$\text{Ca}_9(\text{PO}_4)_{6-x}(\text{HPO}_4)_x(\text{OH})_x$	Cements, coatings, composites	
<i>am</i> -TCP (amorphous TCP)	$\text{Ca}_3(\text{PO}_4)_2, \text{nH}_2\text{O}$	Cements, coatings, composites	

Adapted from Rey, C., Combes, C., Drouet, C., Somrani, S., 2008. Chapter 15 – Tricalcium phosphate based ceramics. In: Kokubo, T. (Ed.), *Bioceramics and their Clinical Applications*. CRC & Woodhead Publishing Limited, pp. 326–366.

composition. The stability of Posner's clusters has been confirmed by theoretical calculations (Trebourg *et al.*, 2000). They consist in a central column of Ca^{2+} ion surrounded by six oxygen atoms arising from six phosphate groups and stabilized with eight additional Ca^{2+} ions distributed at the periphery. These clusters seem to constitute a basic building unit of several calcium phosphate phases (apatite, OCP, and crystalline TCPs). The presence of water is an intrinsic feature of am-TCP which should correspond to a hydrated TCP phase ($\text{Ca}_3(\text{PO}_4)_2 \cdot n\text{H}_2\text{O}$) involving two types of bound water: loosely bound water molecules and the ones inside the amorphous particles which are tightly bound (Eanes, 1970; Sedlak and Beebe, 1974).

Ap-TCP is the low-temperature crystalline form derived from the crystallization in aqueous environment of am-TCP associated with an internal hydrolysis of phosphate groups (Heughebaert and Montel, 1982; Heughebaert, 1977) according to the following chemical equation: $\text{PO}_4^{3-} + \text{H}_2\text{O} \rightarrow \text{HPO}_4^{2-} + \text{OH}^-$ and leading to a crystalline apatite with equal amount of HPO_4^{2-} and OH^- , and consequently with a Ca/P ratio equal to 1.5.

The two major crystalline phases of TCP involved in bioceramics are α and β -TCP. β -TCP is a stable TCP phase which crystallizes in the rhombohedral system (space group $R3c$) with 21 formula units $\text{Ca}_3(\text{PO}_4)_2$ per hexagonal unit cell (Dickens *et al.*, 1974; Elliott, 1994). An interesting structural feature of β -TCP is the presence of columns of ions (anions and cations) parallel to the c -axis. It is worthwhile noting that a great amount of calcium ions (generally reported up to 15%) in β -TCP can be substituted by Mg^{2+} ions without major structure alteration, leading to a Mg- β -TCP phase (Clement *et al.*, 1989). Other bivalent cations can substitute for calcium in β -TCP: Zn^{2+} and Sr^{2+} being among the most interesting ones (Bigi *et al.*, 1997; Ito *et al.*, 2005). Zn^{2+} can substitute for calcium up to 20% and Sr^{2+} up to 80%. β -TCP incorporating some Na^+ ions ($\text{Ca}_{10}\text{Na}(\text{PO}_4)_7$ and up to 2.11% Na^+), has also been synthesized (Obadia *et al.*, 2011).

α -TCP is a metastable TCP phase crystallizing in the $P2_1/a$ monoclinic space group. The unit cell comprises 24 formula $\text{Ca}_3(\text{PO}_4)_2$ units (Mackay, 1953). As for β -TCP, α -TCP structure is also characterized by the presence of columns of ions (Ca^{2+} and PO_4^{3-}) parallel to the c -axis (Mathew *et al.*, 1977). A structural relationship with apatite can be derived by the replacement of cation columns with anion columns as described by Elliott (1994). Ionic substitutions in α -TCP have been less investigated than in β -TCP. Mostly, Zn^{2+} has been reported to substitute for Ca^{2+} (Ito *et al.*, 2001) and silicate for phosphate (Reid *et al.*, 2006; Sayer *et al.*, 2003).

TCP Powders Synthesis

The production of TCP-based ceramics requires first the synthesis of TCP precursor powder and then powder processing to produce cohesive bioceramics (dense or macroporous ceramics, coatings, cements or composites) for bone substitution applications.

Generally, two different TCP powder synthesis routes can be distinguished depending on the amorphous or crystalline TCP phases to be prepared: precipitation in solution (wet route) under controlled experimental conditions (pH, temperature, ion concentrations...) to synthesize the low-temperature phases (am- and ap-TCP), and the dry high-temperature route in particular, but not exclusively, for the synthesis of α - and β -TCP.

Synthesis of am-TCP

Am-TCP can be prepared by various solution-mediated routes. One of the most convenient preparation methods is by double decomposition, in aqueous media at ambient temperature and pH close to 10, between a calcium salt solution and a hydro-genphosphate salt solution (Heughebaert, 1977; Somrani *et al.*, 2005). It can also be obtained in hydroalcoholic medium (Lebugle *et al.*, 1986; Rodrigues and Lebugle, 1998); and the presence of ethanol in the precipitation medium influences the composition of the amorphous phase, especially its HPO_4^{2-} content and Ca/P ratio (Fellah and Layrolle, 2009; Rodrigues and Lebugle, 1998). A sol-gel route in ethanol was also reported to synthesize am-TCP with various Ca/P ratios which then will control the CaP crystalline phase formed after heating, typically at 1100°C in air for 5 h (Fellah and Layrolle, 2009). The main difficulties in the preparation of am-TCP are related to its instability and reactivity. Generally, am-TCP cannot be obtained at neutral or slightly acidic pH. However, it can be stabilized by various mineral ions or organic molecules which can be added in the precipitating and/or washing solutions (Holt *et al.*, 1989). Due to its reactivity and rather high water content, precipitated am-TCP is generally freeze-dried and stored at -18°C to prevent any further evolution. Dry, heated am-TCP can however be stored at room temperature.

Am-TCP can also be obtained by a dry high-temperature route, through rapid quenching of melted calcium phosphate (Ranz, 1996). However, in practice other anions such as O^{2-} are also observed in such high temperature amorphous phase, increasing its Ca/P atomic ratio (> 1.5) especially in plasma sprayed coatings of HA.

Am-TCP can also easily incorporate "foreign" ions through ionic substitutions (carbonate, Mg^{2+} , pyrophosphate, Ag^+ ...) with ions from the preparation solutions (Greenfield and Eanes, 1972).

Synthesis of ap-TCP

This compound is formed from the crystallization of am-TCP in aqueous medium. An internal hydrolysis of PO_4^{3-} phosphate ions occurs according to the following chemical reaction (Heughebaert, 1977; Heughebaert and Montel, 1982): $\text{PO}_4^{3-} + \text{H}_2\text{O} \rightarrow \text{HPO}_4^{2-} + \text{OH}^-$ leading to a crystalline apatite with equal amount of HPO_4^{2-} and OH^- according to the chemical formula $\text{Ca}_9(\text{PO}_4)_{6-x}(\text{HPO}_4)_x(\text{OH})_x$ corresponding to a non-stoichiometric calcium deficient hydroxyapatite family (Rey *et al.*, 2007).

Ap-TCP can be prepared by the methods described for am-TCP powder synthesis, except for the drying step which has to be carried out in an oven at 80°C in order to allow the internal hydrolysis and crystallization to occur (Heughebaert, 1977; Lebugle *et al.*, 1986). Several ionic substitutions are possible in ap-TCP as in other apatitic compounds.

Synthesis of α - and β -TCP

α -TCP and β -TCP phases can be obtained by a suitable high-temperature treatment of am-TCP and/or ap-TCP or, more generally, any mixture of calcium phosphate salts with the appropriate Ca/P ratio (Vallet-Regi *et al.*, 1997). A thermal treatment of am-TCP and ap-TCP phases at 900°C, in air for several hours, leads indeed to the formation of β -TCP with a high purity. α -TCP and β -TCP powders cannot be directly precipitated in aqueous systems but recently pure β -TCP platelet crystals were obtained within minutes at moderate temperature (150°C) by precipitation in ethylene glycol (Galea *et al.*, 2014).

α -TCP is generally obtained by heating β -TCP above 1125°C (the transition temperature for $\beta \rightarrow \alpha$ phase), followed by rapid quenching. It is interesting to note that α -TCP can also be obtained transitorily by heating am-TCP at temperatures lower than 1125°C (between 630 and 700°C), but this method leads generally to a product containing traces of β -TCP (Carrodeguas and De Aza, 2011; Eanes, 1970; Somrani *et al.*, 2003).

TCP-Ceramics Processing

Dense and macroporous ceramics

TCP powder sintering has been less studied than that of HA. The main difficulty in sintering β -TCP ceramic is related to the transition temperature of the β -TCP phase to the α -TCP phase which is accompanied by crystal expansion generating mechanical stresses and consequently cracks within the ceramics (Champion, 2013). For pure TCP, this transition occurs at 1125°C, however it can be shifted toward higher temperature in the presence of trace element impurities such as Mg, Fe, Mn and Zn thus facilitating the sintering process at higher temperatures. Another issue is related to the fact that the reverse transformation from α to β -TCP during ceramic cooling at room temperature does not occur in the same conditions as the initial transformation. Grain growth and reversible conversion into α -TCP is enhanced above 1250°C which compromises the densification and mechanical properties of the ceramic. Usually β -TCP powders are sintered between 1100°C and 1250°C depending on the characteristics of the initial powder and the expected final density of the ceramic (Fig. 4). Densification starts at about 750°C and the highest sintering rate is reached at about 950–1000°C (Champion, 2013). The composition of the initial powder is also a determinant parameter: an excess of calcium (Ca/P > 1.52) facilitates the transformation into α -TCP and Ca/P < 1.42 led to the formation of calcium

Fig. 4 Review on sintering trajectories of β -TCP and BCP ceramics. From Champion, E., 2013. Sintering of calcium phosphate bioceramics. *Acta Biomaterialia* 9, 5855–5875.

pyrophosphate (β -Ca₂P₂O₇) inclusions which slows down the sintering process. Addition of calcium pyrophosphate in the range 0.5–3 wt% enables sintering of β -TCP at higher temperature (1200°C) without transformation into α -TCP; the ceramic obtained has a relative density of 95% (Ryu *et al.*, 2002). Sintering conditions were shown to have an impact on the mechanical behavior of β -TCP ceramics (Wang *et al.*, 2004).

Hot pressing (HP) sintering and non-conventional sintering by SPS of pure β -TCP have been investigated with the objective to lower the sintering temperature while avoiding phase transformation (Drouet *et al.*, 2006; Zhang *et al.*, 2008).

α - and β -TCP biphasic ceramics with controlled α/β ratio can be prepared by reactive sintering of hydroxyapatite (HA) and dicalcium phosphate mixtures impregnated either with Mg-acetate or Mg-nitrate solution stabilizing the β -TCP phase (Famery *et al.*, 1994).

Several methods have been developed to prepare macroporous TCP-based bioceramics with interconnected pores (ranging between 150 and 400 μ m in diameter) allowing cell seeding and/or migration, vascularization and bone ingrowth and also a control of ceramic resorption: ceramic foams (using hydrogen peroxide, carbon dioxide...), solid/solid reaction, ceramic slurry impregnation of polymer porosifier skeletons which leave macropores by heating at temperature below 200°C (sponge, scaffold of PMMA beads...), ice-templating and more recently additive manufacturing like robocasting or microstereolithography. In addition, the preparation of macroporous β -TCP blocks using α -TCP-oil emulsions and sintering at 1250 °C has been reported (Bohner, 2000). Porous α -TCP ceramic can be prepared using replica of porous structure (polyurethane sponge) and conventional sintering of β -TCP above 1100°C (Kitamura *et al.*, 2004). The macroporous TCP bioceramics exhibit generally a low resistance to compression, roughly related to their porosity, which does not allow their direct use in load-bearing applications. The pore volume rarely exceeds 50% (Park *et al.*, 2012; Sous *et al.*, 1998) but can occasionally reach 80%; in addition to the mechanical behavior, it determines the rate of resorption and cellular rehabilitation.

Cements

Currently, the second most important use of TCP compounds is in ionic self-setting cements able to set and harden in a living body and most of them can be injected. Despite their poor mechanical properties, they offer a number of advantages and are increasingly used in clinical practice. Various TCP phases (am-, α - or β -TCP) are involved in many calcium phosphate cement compositions, already commercialized or not. Especially, am- and α -TCP are involved in several cement compositions due to their fast hydrolysis reactions leading to poorly crystalline apatite crystals formation (often similar to ap-TCP) and entanglement responsible for cement hardening. α -TCP has been shown to be stabilized by the presence of silicon which prevents the $\beta \rightarrow \alpha$ reverse transformation during cooling (Mestres *et al.*, 2012). Both Si-doped α -TCP and α -TCP hydrolyze to a calcium-deficient hydroxyapatite during cement setting and hardening, but the setting rate of Si- α -TCP based cement proved to be slower than with α -TCP based cement (Motisuke *et al.*, 2017). Biphasic HA/ β -TCP cement has been prepared with different phase ratios from self-setting α -TCP/ β -TCP pastes (Gallinetti *et al.*, 2014). Also, the association of α -TCP cement with gelatin increases the cement setting rate and its mechanical properties (Bigi *et al.*, 2004). β -TCP is the main constituent of DCPD cements and sometimes used as inert additive in other types of CaP cements. One of the main drawbacks compared to ceramic blocks is the preparation of the paste and (most generally) the absence of macropores allowing cell rehabilitation, but the main advantage is their ability to fill any kind of bone defects and their injectability allowing mini-invasive surgical procedures. Although the hardening reactions are generally correctly described *in vitro*, the alterations of these reactions *in vivo* are not well known when the cement paste is in contact with body fluids, and the diffusion of mineral ions and/or organic additives from the cement to adjacent tissues.

Coatings

Although formed in several coating processes, especially in plasma sprayed HA, TCP compounds have not yet been commercialized as thermal coatings. Low temperature deposition involving am- and ap-TCP-like compounds (Barrere *et al.*, 2004) has been proposed. Several authors studied β -TCP coating on bioinert bioceramics (zirconia) or metals/alloys (magnesium alloys, titanium, gold) to improve their *in vitro* and *in vivo* biological properties. Stefanic *et al.* used a wet deposition route followed by a thermal treatment at a temperature ranging between 800 and 1200°C which could control the β -TCP coating topography and physicochemical properties (dissolution, protein adsorption capacity, bioactivity in SBF) (Stefanic *et al.*, 2014). Other authors also implemented wet routes for preparing the metallic surfaces (alkali treatment) and then formed the β -TCP coating in a super-saturated calcium phosphate solution or by electrodeposition using a β -TCP suspension both followed by a heat treatment at 400°C (Chai *et al.*, 2012; Chen *et al.*, 2014; Jiang *et al.*, 2015; Pang *et al.*, 2018). β -TCP coating was also reported to be obtained by RF magnetron sputtering or plasma spray (Lim *et al.*, 2018; Lin *et al.*, 2001).

Composites

TCP compounds (mainly α -, β -TCP and am-TCP) are also used as mineral ions releasing substances in polymer materials although such composites have received little commercialized applications. Many types of polymeric materials have been proposed mainly degradable natural or synthetic polyesters (polylactic, polyglycolic acids, poly- ϵ -caprolactones, etc.) and natural polymers or proteins (collagen, chitosan, alginate,...) (Aunoble *et al.*, 2006; Kikuchi *et al.*, 2004b; Luginbuehl *et al.*, 2005; Matsuno *et al.*, 2006; Van Den Vreken *et al.*, 2006; Zhang and Zhang, 2001). The advantages of these associations have not always been demonstrated (Ekholm *et al.*, 2006).

Main Physicochemical Properties of TCP Phases

Several TCP physicochemical properties of interest for TCP ceramics processing (thermal properties) and their interaction with biological fluids (solubility and evolution in aqueous medium) and bone tissue (see in the Section “Biological Properties”) will be presented in the next section.

Solubility

All TCPs are considered as more soluble than stoichiometric hydroxyapatite, however a precise solubility product has not yet been determined in the case of am- and ap-TCP. For the latter compound it depends probably on the hydrolysis ratio and its stoichiometry. A broad range of data on the solubility of am-TCP is available; some of the reported values could have been altered due to the hydrolysis reaction of this very unstable phase. The most relevant values reported are related to the work of Somrani *et al.* (2005). As expected, this phase is much more soluble than the crystalline TCP phases.

The solubility behavior of α - and β -TCP has been fully investigated (Fowler and Kuroda, 1986; Gregory *et al.*, 1974). As a general trend, the solubility of these phases was found to decrease in the order α -TCP > β -TCP > Ca-deficient apatites > HA (Ducheyne *et al.*, 1993). Considering the general concept that biological resorbability of calcium phosphates is determined by their solubility, all TCPs are bioresorbable (LeGeros, 1991).

Substituted β -TCP, containing Zn and Mg, have been shown to exhibit a lower solubility than the non-substituted one depending on the substitution ratio (Ito *et al.*, 2002). Additionally, the kinetics of dissolution of β -TCP seems very sensitive to the presence of foreign ions in the solution, especially Mg^{2+} and Zn^{2+} , and a concentration of Zn^{2+} as low as $2 \times 10^{-6} \text{ mol L}^{-1}$ has been shown to completely inhibit its dissolution (Tang *et al.*, 2001). For a given ion-doping molar content, Mg-doped β -TCP was reported to be more soluble than Zn-doped β -TCP (Li *et al.*, 2009b). Recently, the dissolution properties of non-doped and Mg-doped β -TCP dense ceramics in acidic solution (pH 4.4) have been compared, demonstrating the key role of doping (especially Mg-doping) and grain orientation on the process and kinetics of resorption (Gallo *et al.*, 2019).

TCP phases evolution in aqueous medium

When immersed in solution, α -TCP and am-TCP show a strong tendency to evolve towards a more stable phase through a hydrolysis process for which solution parameters such as pH, ion concentrations and temperature are known to play a major role. In alkaline and neutral pH conditions, am-TCP progressively transforms into non-stoichiometric hydroxylated apatites (Eanes and Meyer, 1977). The presence of some ionic species such as Mg^{2+} , CO_3^{2-} , $\text{P}_2\text{O}_7^{4-}$ which inhibit apatite crystal growth was shown to delay this hydrolysis process (LeGeros *et al.*, 2005). The hydrolytic conversion rate of am-TCP into apatite depends strongly on the temperature (Heughebaert, 1977; Somrani *et al.*, 2005) which thus controls the setting reaction of am-TCP based cements (Knaack, 1998).

α -TCP hydrolyzes also rapidly in aqueous solution (Monma, 1980; Monma *et al.*, 1981). The hydrolysis products are generally OCP and non-stoichiometric apatite, although dicalcium phosphate anhydrous (DCPA or monetite) and dicalcium phosphate dihydrate (DCPD or brushite) can also form.

In contrast, β -TCP does not show a tendency to hydrolyze rapidly in solution at physiological temperatures. This behavior can be linked to its solubility product below that of blood plasma (larger value of $-\log [K_{sp}]$) in contrast to the other TCP phases and particularly α - and am-TCP (Rey *et al.*, 2008).

Thermal stability of TCP phases

No variation of the Ca/P ratio of TCP phases can occur on heating. Among the TCP phases, α -TCP is known as the high-temperature stable form in the 1125°C to 1430°C temperature range (Welch and Gutt, 1961). Under 1125°C, β -TCP is the stable TCP phase. ap-TCP can be seen as the low-temperature crystalline form of am-TCP (e.g., upon drying at 80°C). On heating at temperatures higher than 750°C, this phase transforms into β -TCP (Destainville *et al.*, 2003). Am-TCP is a quite unstable phase and hydrolyzes easily into ap-TCP in the presence of small amounts of water at room temperature. Am-TCP remains however amorphous when heated up to ca. 630°C (Eanes, 1970). Above this temperature, it crystallizes first into the metastable α -TCP generally associated with small fractions of β -TCP at 800°C, and then into pure β -TCP. However, am-TCP enriched with Mg (or containing other elements stabilizing the β -TCP phase such as Fe and Zn) transforms directly into the β -TCP phase without the intermediary formation of α -TCP.

Surface properties of TCP

Only few data are available to-date on the surface properties of TCP phases, despite their high involvement in the biomaterials field. Regarding the literature concerning the surface properties or reactivity of TCPs, most studies deal with either adsorption or ion exchange processes, but the elucidation of the corresponding mechanisms and the relationship with intrinsic surface properties of the TCP phases involved are only rarely addressed.

The effect of recombinant human transforming growth factor-beta1 (rhTGF-beta1) adsorbed onto TCP-coated implants (0.3 μg of rhTGF-beta1) was followed in a dog model (Lin *et al.*, 2001). The adsorption of various proteins on β -TCP and other calcium phosphates was also investigated (Ohta *et al.*, 2001). The total number of calcium sites on β -TCP was found to be significantly smaller than on the other calcium phosphates tested, including hydroxyapatite. The association of bisphosphonate with β -TCP and a mixture of HA and β -TCP has been investigated (Josse *et al.*, 2005). A high amount of zoledronate was associated

with β -TCP powders and the released concentration of phosphate in solution was shown to be directly related to the amount of zoledronate loaded on β -TCP.

Biological Properties

In vitro cell tests on TCPs

Many cell culture studies on TCP ceramics have been published involving osteoblast, osteoclast and bone cell precursors. Often these studies have been made on poorly characterized TCP samples (grain size, impurities, microstructure, surface roughness); moreover they implied different cell lines and different methodologies. It is therefore not possible to correlate these rather large sets of data and to link the observations with physical-chemical characteristics of the materials. In addition, alterations of TCPs surface ceramics in cell culture media have been reported which are susceptible to modify cell behavior during the course of the experiments. A follow-up of the mineral composition of the cell culture medium and a re-analysis of the ceramic surface after cell culture could probably clear up some contradictory results.

It has been generally observed that TCP ceramics are not cytotoxic on contact with extract fluids. In the presence of TCP particles, which could be released from cement powders or from resorbing ceramics, the osteoblast cell behavior depends strongly on the amount and size of particles. Massive amounts of small particles impair cell growth (Pioletti *et al.*, 2000; Sun *et al.*, 1997) and may cause cell death whereas small amounts of α -TCP powders have been shown to favor osteoblast proliferation and expression, which is possibly related to the release of mineral ions, especially calcium and phosphate ions, acting directly on cells (Ehara *et al.*, 2003). Osteoblast cell cultures on composite samples (biphasic calcium phosphates, TCP and collagen or polymers) give generally better results than on the raw materials. Ion-substituted TCP (Zn- β -TCP, Mg- β -TCP, Si- α -TCP cement) have also been claimed to improve osteoblast attachment and proliferation sometimes related to an optimal ion substitution ratio (Camire *et al.*, 2006; Ito *et al.*, 2000; Singh *et al.*, 2014), compared to the pure TCP. The role of surface energy and topography of β -TCP on the osteoblast cells has also been studied *in vitro* (dos Santos *et al.*, 2008, 2009).

It has been shown that CaP material characteristics (composition, solubility, grain size and crystallinity) as well as surface features (topography, roughness, pore size, wettability and surface energy) influence osteoclasts adhesion and resorption activity but only very few data have been published concerning osteoclast behavior on TCP phases. Some authors failed to observe any activity on the surface of α - and β -TCP despite alterations of the calcium and phosphate concentration in the cell culture medium (Doi *et al.*, 1999). A possible reason for this failure could be the ion release, and probably the existence of an alkaline surface reaction related to the surface hydrolysis, inhibiting osteoclast activity. In other cases, however, osteoclast attachment and resorption activity has been described, evidencing a much stronger degradation of β -TCP than HA (de Bruijn *et al.*, 1994; Monchau *et al.*, 2002), related to the rate of dissolution of the calcium phosphates. Such data seem in agreement with *in vivo* studies. Recently, Gallo *et al.* compared the results of an osteoclast resorption assay with a dissolution test of β -TCP samples in acidic conditions (Gallo *et al.*, 2019).

The possible use of α -, β - and Zn-containing β -TCP as scaffolds for bone tissue engineering has been investigated using bone marrow cells (Dong *et al.*, 2002; Ikeuchi *et al.*, 2003; Jensen *et al.*, 2015; Kim *et al.*, 2017; Niemeyer *et al.*, 2004). These ceramics have been shown to exhibit good biological properties favoring cell adhesion, proliferation and differentiation. Implants seeded with precursor cells have shown the ability to generate bone tissues in non-osseous sites (Kasten *et al.*, 2005) and the rate of bone healing has been shown to be higher using cell-seeded ceramics.

In vivo studies

The literature on *in vivo* studies agrees generally on the relation between the degradation rate of TCPs and their dissolution kinetics including structural and microstructural parameters such as crystal size, particle size and porosity/pore size of the ceramics (Duan *et al.*, 2017; Lapczynska *et al.*, 2014; Zhang *et al.*, 2014). α -TCP has been shown to be more easily resorbed than β -TCP *in vivo* (Yamada *et al.*, 2007) and Zn- and Mg-substituted β -TCPs exhibit generally a lower resorption rate *in vivo* related to the effects of the substitutions on the solubility (Ito *et al.*, 2002). Hydrolysis into less soluble compounds may occur rapidly *in vivo*, especially for am- and α -TCP, affecting their biodegradation.

Generally bone formation is observed on degraded β -TCP and α -TCP implant surface on contact with the materials and sometimes at a distance of the ceramic surface (Galois and Mainard, 2004; Kihara *et al.*, 2006; Neo *et al.*, 1998). This behavior could be related to the resorbability of TCP implants which could occur at different rates from that of bone formation, possibly because of the involvement of different resorption processes, and the inability of TCP to promote apatite nucleation.

In some cases, an osteoinductive behavior of raw β -TCP has been suggested (Tsukanaka *et al.*, 2015; Yuan *et al.*, 2001) however other authors have reached opposite conclusions. Association of growth factors such as BMP (bone morphogenetic protein) with TCP ceramics provides however an osteoinductive behavior (Wu *et al.*, 1992).

The main difficulty concerning especially α -TCP and am-TCP is their evolution *in vivo*. These are rarely considered but they have probably a strong impact on their biological behavior. In addition to histological investigations, physical-chemical characterization of the retrieved implants should be performed for better apprehending the modifications undergone and the surrounding bone neoformation.

Fig. 5 SEM micrographs of macroporous BCP ceramic (mean pore diameter: 565 μm ; total porosity: 50%) implanted 12 weeks in critical bone defect (rabbit femur) (A) showing bone ingrowth in the pores both at the periphery (B) and within the implant (C). BCP (white); native and newly formed bone (gray); non mineralized tissue (black). From Bouler, J.M., Pilet, P., Gauthier, O., Verron, E., 2017. Biphasic calcium phosphate ceramics for bone reconstruction: A review of biological response. *Acta Biomaterialia* 53, 1–12.

Biphasic Calcium Phosphate Ceramics: HA/ β -TCP

Biphasic calcium phosphate (BCP) ceramics associating a rather soluble calcium phosphate phase, β -TCP, with a more stable phase, HA, allow a better control of bioactivity and biodegradation rate thanks to their physicochemical characteristics (HA/ β -TCP ratio, micro- and macroporosity and the interconnection of pores) and have proven to be efficient in numerous clinical indications especially in the form of macroporous granules or monoliths (Fig. 5) (Bouler *et al.*, 2017; Daculsi *et al.*, 2003; LeGeros *et al.*, 2003). The HA/ β -TCP ratio is known as the main parameter controlling not only the bioresorption rate but also the biological properties of BCP ceramics through the effect of the released ions on bone progenitor cells. The properties of BCP ceramics vary depending on the sintering process and parameters which control the microstructure, phase composition and crystal defects within the ceramic (Bouler *et al.*, 2000).

BCP with different HA/ β -TCP ratios can be prepared by mechanical mixing and co-sintering of HA and β -TCP powders in desired quantities or by chemical methods producing calcium-deficient apatites ($\text{Ca}_{10-x}(\text{HPO}_4)_x(\text{PO}_4)_{6-x}(\text{OH})_{2-x}$) followed by sintering. The ability of BCP to be sintered is lower than that of the separated HA or β -TCP phases; a higher temperature (for example at least 1250°C) is needed to sinter dense BCP ceramics (Bouler *et al.*, 2000). To avoid β -TCP to α -TCP transformation in this temperature condition, magnesium oxide is commonly added to stabilize the β -TCP phase (Ryu *et al.*, 2004). The BCP composition obtained after sintering depends on the calcium deficiency of the unsintered biological or synthetic calcium-deficient apatite and on the sintering temperature.

The HA/ β -TCP ratio of BCP ceramics controls both the ceramic resorption rate and the release of ions in the environment of bone cells which could also trigger the biological properties.

BCP macroporous ceramics are processed by gel casting or addition of sacrificial organic particles (polymer, naphthalene, sucrose particles...), to be degraded by a thermal treatment before sintering, depending on the targeted porosity and final mechanical strength, and then sintered at high temperature. Sintering of BCP at lower temperature has been investigated by conventional and microwave sintering leading to microporous ceramics, but the sintering is not completed (Li *et al.*, 2009a). Micro and macroporous BCP ceramics are expected to present better biological properties.

To improve BCP granules handling, their association with a hydrosoluble polymer or silanized hydroxypropyl methyl cellulose gel allows obtaining a non self-hardening or self-hardening injectable bone substitute, respectively (Struillou *et al.*, 2011). Other associations of BCP granules with fibrin glue to obtain a composite or with other calcium phosphate phases to obtain a self-setting cement have also been investigated (Saffarzadeh *et al.*, 2009).

Conclusion and Perspectives

Two main families of calcium phosphate compounds are particularly investigated for biomedical applications, and especially for bone repair: apatites (involving not only stoichiometric HA but also non-stoichiometric/biomimetic phases) and tricalcium phosphates. The most recent developments aim at proposing new processing routes and improving their biological properties. Three main axes are specially investigated: their substitution with bioactive ions, their combination with active molecules, and their association with cells in the scope of tissue engineering. The ion-substituted route leads to compounds which have shown interesting advanced properties and it is probable that they will receive an industrial development in future years. One of the main advantages of these inorganic materials is their low cost and stability to sterilization procedure and their excellent storage properties. Local delivery of active (bio)molecules including growth factors from composite materials based on apatite or TCPs ceramics is widely investigated. Despite a high cost and uncertainties on stability of such biologically active molecules, they will probably appear on the market for some dedicated applications, especially in the case where bone repair potential is impaired and in old patients; regulatory aspects are however particularly drastic with the use of growth factors. A difficulty in the case of BMP-containing HA or TCP bioceramics is indeed the need of a high concentration of growth factor, much higher than physiological doses. There are probably progresses to be made in the optimization of growth factor release and control and also probably in considering the associations of several active molecules with complementary and/or synergistic activities. Because of their resorbability, porous TCP ceramics have been used with success for tissue engineering of bone tissue. Despite the cost of tissue engineering strategy, apatitic and TCP-based scaffolds are widely studied and developed for the personalized repair of critical size defects in bone tissue especially considering the very recent development of additive manufacturing for bioceramics processing. Beyond bone repair, other medical domains are also emerging such as (nano)medicine and cell therapy where bio-inspired CaP compounds can cumulate a high tailorable reactivity and an intrinsic biocompatibility.

Summary

Calcium phosphates (CaPs) are biominerals found in living organisms. Synthetic analogs can be prepared for biomedical applications like bone substitution and (nano)medicine. Biomimetic nanocrystalline apatites exhibit a high bioactivity while stoichiometric hydroxyapatite (HA) is thermodynamically very stable. Other CaPs are also relevant to medicine like tricalcium phosphates (TCPs, especially the high temperature α and β forms or the low temperature forms, amorphous TCP and apatitic TCP). These apatitic and tricalcic compounds are the most used CaPs in the biomedical field, and offer a large panel of bioceramic-based systems with diverse characteristics (mechanical, biological, chemical, thermodynamic...) to comply with clinical needs.

Introduction

Apatite was the first calcium phosphate recognized as mineral specie. It was discovered in 1786 by Abraham Gottlob and named by him as “Apatao”. From the ancient greek that means “to mislead” because it had previously been confused for other minerals, namely beryl, tourmaline, chrysolite, amethyst, fluorite, etc. Nowadays, apatite is the name for a group of minerals with the same crystallographic structure. In the case of calcium phosphates (CaP), the term “apatite” involves CaP with Ca/P ratios within 1.5–1.67. The main CaP phases and their corresponding formulas are summarized in [Table 1](#). CDHA, HA, FA, and OA belong to the apatite’s group while MCPM, MCPA, DCPD, and DCPA belong to the acid phosphates group. CaP are an interesting family of compounds in many fields of science and technology, including geology, chemistry, biology and medicine due to their natural abundance and their presence in the living organism ([Dorozhkin, 2013a](#)). The present chapter will be focused on the revision of CaP uses for biomedical applications and their progresses in the biomaterials field thanks to the advances achieved in their synthesis and processing and making them capable of addressing new challenges of medicine.

Calcium Phosphates in the Field of Biomaterials

CaP are of a special importance since they are the most important inorganic constituents of hard tissues in vertebrates. In the form of a poor crystalline, non-stoichiometric, ion-substituted calcium-deficient hydroxyapatite (CDHA, commonly referred to as “biological apatite”), CaP are present in bones, teeth and tendons of mammals to give these organs stability, hardness and function ([Dorozhkin, 2013a](#)). That is why these CaP are characterized by being biocompatible what makes them extremely interesting for medical applications.

CaP have been widely studied from a biological, structural, and morphological point of view and nowadays, they are commonly applied in orthopedic and maxillofacial application as well as in dentistry due to biocompatible and osteoinductive properties apart from their biocompatibility ([Dorozhkin, 2013a](#)).

Especially in the field of bone restoration and regeneration applications, the research in CaP has been driven due ageing challenge faced by the actual society. It is well known that all the tissues suffer a progressive deterioration with age. In bone tissue, this process is named osteoporosis. It is a worldwide disease which mainly affects to humans older than 50. The process is especially severe in women because of the menopause. It can result in bone fractures which involve patient disability or even death in the worst cases. Moreover, the use of new transports and the practice of extreme sports during the last decades have increased the number of accidents whose assistance involves orthopedic surgery. For these reasons, it has been experienced an increase in the demand of bone grafts and advances in surgical practice.

The first in vivo tests performed with CaP as artificial material to repair defects created surgically were made in 1920 by the surgeon Fred Houdlette Albee, who can be considered the father of bone grafts. However, it won’t be until 1960 when the interest for ceramics as potential bone grafts has grown owing to their biomechanical properties. The first goal of bioceramics was to replace part of bones, so the requirement was that the physiological environment must tolerate them. They must be able to resist the mechanical loads of implanted individuals in physiological conditions during years of use ([Sastre et al., 2004](#)).

Table 1 Summary of CaP phases, their corresponding Ca/P molar ratios, abbreviations and formulas

Ca/P atomic ratio	Compound	Typical abbreviations	Chemical formula
0.5	Monocalcium phosphate monohydrate	MCPM	$\text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O}$
0.5	Monocalcium phosphate anhydrous	MCPA or MCP	$\text{Ca}(\text{H}_2\text{PO}_4)_2$
1.0	Dicalcium phosphate dihydrate, Brushite	DCPD	$\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$
1.0	Dicalcium phosphate anhydrous, Monetite	DCP, DCPA	CaHPO_4
1.33	Octacalcium phosphate	OCP	$\text{Ca}_8(\text{HPO}_4)_2(\text{PO}_4)_4 \cdot 5\text{H}_2\text{O}$
1.5	β -Tricalcium phosphate	β -TCP	$\beta\text{-Ca}_3(\text{PO}_4)_2$
1.5	α -Tricalcium phosphate	α -TCP	$\alpha\text{-Ca}_3(\text{PO}_4)_2$
1.2–2.2	Amorphous calcium phosphates	ACP	$\text{Ca}_x\text{H}_y(\text{PO}_4)_z \cdot n\text{H}_2\text{O}$ $n = 3 - 4.5$; 15%–20% H_2O
1.5–1.67	Calcium-deficient hydroxyapatite	CDHA or Ca-def HA	$\text{Ca}_{10-x}(\text{HPO}_4)_x(\text{PO}_4)_{6-x}(\text{OH})_{2-x}$ ($0 < x < 1$)
1.67	Hydroxyapatite	HA or HAp	$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$
1.67	Fluorapatite	FA or FAp	$\text{Ca}_{10}(\text{PO}_4)_6\text{F}_2$
1.67	Oxyapatite	OA, OAp or OXA	$\text{Ca}_{10}(\text{PO}_4)_6\text{O}$
2	Tetracalcium phosphate	TetCP	$\text{Ca}_4(\text{PO}_4)_2\text{O}$

In addition, implants need to fix to the surrounded tissue so bone bonding is also a mandatory requirement. In 1967, Prof. Hench started his research through the modification of the chemical composition of ceramics and glasses to provide then chemical reactivity in contact with the physiological media, with the aim to promote bone bonding. The concept of bioactivity appears. In 1971 appeared the first bioactive glass, named Bioglass® and in 1984 Hench and Wilson include the Hydroxyapatite (HA) inside of the bioactive ceramics group. Hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), has been widely used in the field because its chemical composition is quite similar to mineral phase of bones. It has an ionic character and its crystalline structure can be described as a hexagonal packaging of oxygen atoms where cations are placed on the tetrahedral and octahedral sites (Sastre *et al.*, 2004).

Due to the chemical similarity of CaP and the inorganic phase of bones and teeth, they possess bone-bonding ability. For this reason, they have been processed as coatings in the surface of load-bearing implants.

Furthermore, beyond replacing the lost bone, the new challenges facing science is regeneration (Peppas and Langer, 1994). New concepts such as biodegradation, resorption or osteoinduction appear. Modern grafts should act as temporal support for cells and promote bone regeneration while material is resorbed. Then, biodegradability is also an essential property. It is possible to design CaP-based materials with controlled biodegradation rate. Biodegradability is mandatory and HA is a very stable phase under the physiological conditions, which is translated into a low solubility and slow resorption kinetics. Then tricalcium phosphates (TCP) appears. It is the biodegradable CaP par excellence (Sastre *et al.*, 2004). It belongs to the Whitlockites family which correspond to the general formula $(\text{Ca,Mg})_3(\text{PO}_4)_2$. Most of the bioresorbable ceramics, with the exception of plaster or wollastonite (de Aza *et al.*, 1994, 2000), are based on CaP. Their biodegradability increases following the sequence $\text{HA} \ll \beta\text{-TCP} < \alpha\text{-TCP}$.

Moreover, since for cells it is difficult to organize themselves in big defects, nowadays, CaP are designed as three dimensional (3D) porous structures to promote cell colonization, vascularization, and bone formation. (Canillas *et al.*, 2017) For this reason, regeneration has also promoted the need to develop porous 3D structures and has focused the interest of the studies in the development of processing methods to manufacture CaP scaffolds. With the development of additive manufacturing technologies, 3D printing means a revolution in the biomaterials field. In report titled "The disruptive nature of 3D printing" published in the European Commission, the importance of the 3D printing technologies for the development of CaP 3D structures for bone regeneration applications is highlighted. Due to the necessity to produce 3D structures adapted to the requirements and sizes of patients, additive manufacturing allows the manufacture of personalized implants in short times. In the same report the authors point to bioprinting, and specially of hard tissues, as the research placed at the forefront (Bonneau and Yi, 2017).

Finally, recent studies are also focused in the physicochemical properties of CaP. Apart from their chemical composition, particle shape and size or the porous morphology have been studied as key parameters in the cell osteogenesis. The objective of these studies is the development of more biomimetic materials (Barba *et al.*, 2018). Finally, apart from bone substitution and regeneration applications, they have been also suggested as vehicles of drugs, peptides or ADN molecules (Parent *et al.*, 2017).

Synthesis and Processing

Synthesis

As it was previously mentioned CaP are minerals present in the nature and in the hard tissues of vertebrates. The constituting building blocks of bone are composites of biological apatite and molecules of collagen. Calcified tissues, such as bone or dentin contain ~70 wt% apatite and ~20 wt% collagen (Vallet-Regí and González-Calbet, 2004).

Nano-sized CaP represent the basic inorganic building blocks of bones and teeth of mammals. Collagen molecules are self-assembled into fibrils with a periodicity of 67 nm and 40 nm gaps between the ends. Within these gaps, biological apatite takes place and grows in the form of tiny nano-sized plate-like crystals with specific crystalline orientation along the c-axes in parallel to the long axes of the collagen fibrils. This in vivo process of biological apatite formation is named biological mineralization or biomineralization. Biomineralization is the natural method of synthesis of CaP. During this process, organized assemblies of organic macromolecules regulate nucleation, growth and morphology of inorganic crystals. Nanodimensional apatite achieves two main functions: nanometer sizes of mineral particles ensure the optimum strength and maximum tolerance of flaws; moreover, it is a storage of calcium and orthophosphate ions which are available for a wide variety of metabolic functions thanks to the so-called remodeling process. It consists on the constant resorption and formation of biological apatite which are controlled by osteoclasts and osteoblasts respectively.

Apart of biomineralization, the origin of CaP used for medical application can be natural, for example, calcined bovine HA or carboxyhydroxyapatite from the eggshells, and/or synthetic. Most common synthesis methods are based on thermal treatment in solid state (Lin *et al.*, 2014). But there is also a wide range of synthesis methods inspired on the bottom-up approach. The wet chemical precipitation is the most used. Morphology, phase formation and crystallinity of precipitated apatites have been studied in relation with temperature, calcium concentration or pH. Other method commonly used in the synthesis of nanosize CaP is the hydrothermal. Fine-grained single crystals, characterized by high purity, controlled morphology and narrow size distribution can be obtained. Alternative bottom-up synthesis methods can be such as sol-gel (Costa *et al.*, 2012) or solution combustion method (Canillas *et al.*, 2017). The latter allows the design of the shape and size of particles by the control of the redox environment.

Moreover, methods based on the natural nucleation and growth of nanocrystalline apatite between self-assembled collagen fibrils, have been also developed based on the biological apatite formation in mammals. This process has been simulated using macromolecules as templating agents. Precipitation of nanosized apatites from aqueous solutions has been carried out, for

example, in the presence of dissolved polyacrylic acid (Liou *et al.*, 2005), polyvinyl alcohol, amino acids or gelatin. The aim of this type of synthesis is the obtention of biocomposites with structure and mechanical properties similar to bones. It also allows the obtention of complex morphologies. An interesting example is a pH-induced self-assembly peptide-amphiphile, to obtain nanostructured fibrous scaffolds by cross-linking, and following mineralization. C-axes of CDHA crystals grow aligned with the long axes of the fibers similar to biological apatite in bones (Dorozhkin, 2013b).

Most of the CaP synthesized are composed by HA, TCP or mixtures of those. TCP presents three poly-morphs: β , α and α' , from the lowest to the highest stability temperatures and being the last one total reversible in both senses. (Carrodegua and de Aza, 2011) In case of α and β , pure phases as well as controlled mixtures may be obtained with adequate thermal treatment and amount of Mg. $\beta \rightarrow \alpha$ Ca₃(PO₄)₂ transition temperature is increased with Mg (Mg₃(PO₄)₂) and Mg and Si (CaMg(SiO₃)₂) content. (Carrodegua *et al.*, 2010) Moreover, β -TCP phase can be also stabilized with partial Ca substitution for Sr and Zn and α -TCP with partial PO₄³⁻ substitution for SiO₄⁴⁻. (Wang *et al.*, 2018; Bandyopadhyay *et al.*, 2012) Whatever of these phases, possess higher solubility than HA (HA < β -TCP < α -TCP) according with the literature. The vast majority of CaP bioceramics are based on HA both types of TCP and multiphase formulations thereof.

The term BCP (Biphasic Calcium Phosphates) is referring to mixtures of CaP phases. In order to obtain the optimum in vivo bioresorbability this kind of mixture are used. Usually balance of a more stable phase and a more soluble phase are used with the aim to control the bioresorbability. Different biphasic mixtures of HA and β -TCP and α -TCP phases has been considered and also triphasic formulations were included. In fact, the preparation of pure chemicals is difficult and expensive, so CaP bioceramics are multiphasic mixtures where there are one or two major phases. In general, physico-chemical properties of biphasic, triphasic and multiphasic CaP bioceramics depend on the relative amounts of the components. (Daculsi *et al.*, 2009) The most important advantages of biphasic, triphasic and multiphasic CaP bioceramics is the control of the in vivo resorption as well as bioactivity by manipulation of the phase ratios. (Yamada *et al.*, 1997) BCP products with different or similar HA/ β -TCP ratios have been manufactured and they are commercially available as bone graft or bone substitute biomaterials for orthopedic, maxillofacial and dental applications.

Finally, self-setting formulations have drawn great attention due to their easily handling and their biomimetic physicochemical properties with the inorganic phase of bones. Self-setting CaP formulations are mixtures of CaP powders and aqueous solutions such as distilled water, SBF, aqueous solutions of sodium orthophosphates, H₃PO₄ or citric acid. Self-setting process goes through two possible reactions: acidic-base or hydrolysis. In the first case, CaP with relatively acidic behavior reacts with relatively basic one to produce a relatively neutral compound. The second type consists on the hydrolysis of metastable CaP in aqueous media. In both cases, when CaP are placed in the aqueous environment they dissolve and a process of mass transport takes place until supersaturated microenvironment is created with regards to the final product. Crystals obtained by precipitation grow and form microneedles and micropellets of CDHA and DCPD, which provide rigidity to the hardened material (Ginebra *et al.*, 2010).

Depending of the product obtained after setting, cements are divided in two main types: apatite forming formulations and brushite forming formulations. In case of apatite-forming formulations, the products of the setting reaction are poorly crystalline HA, CDHA, or carbonate apatite, if the setting reaction occurs in presence of carbonates. It is thought that the similar chemistry of those products and biological apatite is responsible of their excellent in vivo resorption.

In addition, the setting process occurs at pH values close to the physiological and it contributes to their good biocompatibility. Solubility of these formulations in aqueous solutions is expected to be similar to that of bone mineral. Solubility increases when pH is slightly acid. Moreover, controlled dissolution can be improved by osteoclast. Furthermore, crystals obtained can be easily detached, especially after dissolution and it makes the ingestion by osteoclast and other cells easier. Regarding to the setting time, which is increased on in vivo conditions, it is quite long for apatite forming formulations. It can involve technical complications and, for this reason, an interesting goal consists on decrease their setting time. Different approaches have been suggested, for example, by reducing the amount of liquid phase as low as possible or using additives like H₃PO₄ to decrease the pH and promote the dissolution of CaP.

In the case of brushite forming formulations, the major product of the setting reaction is DCPD. These setting reactions occur by acidic-base process. DCPD precipitates mainly at pH below 6. Consequently, the reaction environments in these formulations are always slightly acidic. Apart from its biocompatibility, Brushite presents higher solubility compared with CDHA. It is translated in a faster degradation and quickly resorption in vivo. The disadvantage is the short setting time that makes its injectability complicated. For this reason, one of the main goals consists on decrease the viscosity.

Finally, monetite based formulations have been developed by acidic-base process to be applied as granulates which provide a 3D structure (Padilla *et al.*, 2015). Inside of brushite cements, monetite has also take great attention. Cements for Monetite-HA mixtures have been developed with the aim to control bioresorption rates.

Processing

As other formulations, CaP might be processed in both dense and porous forms in bulk, as well as in the forms of powders, granules, scaffolds, or coatings. Depending of the requirements they have to be processed in different ways. For example, improved mechanical properties require dense materials while cell colonization, bone regeneration, and vascularization require 3D porous structures such as scaffolds or granules. Powders can be used, for example as raw materials to obtain self-setting formulations or inks for 3D printing. Nanosized particles can be used not only to obtain dense materials but also for drug delivery systems or gene therapy (Parent *et al.*, 2017).

Processing normally consist in two steps, conformation, considering the specifications of the component to produce, and following sintering. Most common shape forming methods include: uniaxial compaction, isostatic pressing, granulation, slip casting, gel casting,

freeze casting, spray drying, polymer replication, extrusion, low pressure injection, dipping or thermal spraying. Also, shaping can be carried out during cooling and solidification of previously melted raw materials. It has to be noted that shape forming of any ceramic products require a proper selection of the raw materials in terms of particle sizes distribution. Sintering is a processing step with great interest to consolidate the shaped forms. During the sintering of CaP, different processes take place in CaP compositions: dihydroxylation, decarbonation, volatile chemicals removal, shrinkage and grain size growth. Chemical changes such as chemical decomposition of acidic orthophosphates by water loss also take place. To obtain improved mechanical properties grain growth and remaining porosity must be minimized during the sintering (Laasri *et al.*, 2010). For this reason, sintering methods such as hot isostatic pressing, microwave, spark plasma sintering or rate controlled sintering have been suggested.

Polymeric-ceramic composites were designed with the objective to get similar mechanical properties to bones since they are a composite material of collagen and hydroxyapatite. Moreover, they have increased the processing possibilities for ceramics. These kinds of composites have been widely studied and developed for biomedical applications. The main reasons to add a polymeric phase are: the improvement of the mechanical properties regarding to the brittleness of ceramics, their easy manufacture as 3D structures and the possibility to include drugs or molecules in their matrix and their ability to control their drug delivering rate. Ceramic powders, granulates or 3D structures can be coated or embed in a polymer matrix. Polymeric processing methods such as freeze-thawing, photopolymerization, melt-extrusion, have been used in the processing of polymeric-ceramic composites (Canillas *et al.*, 2017).

Furthermore, bone regeneration applications need the manufacturing of implants with interconnected porosities, complex geometries and specific sizes. Nowadays, CaP implants with even more complex geometries can be developed thanks to the computer-aided design and additive manufacturing technologies. For example, a digital image of a bone defect in a patient can be used to develop a three-dimensional (3D) structure. The computer reduces the model to slices or layers and 3D structures are constructed layer-by-layer (de Aza *et al.*, 1994). CaP or composites of those with polymers and hydrogels can be printed by using different 3D technologies: VAT polymerization (such as stereolithography), power bed fusion (laser sintering), material extrusion (robocasting or fused deposition modeling) or binder jetting. In many cases, a second sintering step is required involving the sacrifice of the polymer phase (Zhang *et al.*, 2019).

Last advances in robocasting have developed 3D CaP structures with polymer cores to improve mechanical properties. Coaxial needle is used to produce log-pile structures of hollow rods which are following filled with a polymer phase. (Paredes *et al.*, 2019). Moreover, the development of 3D structures with self-setting formulations by robocasting have avoided the sintering step and the manufacturing of more biomimetic structures (Raymond *et al.*, 2018).

New developments on Selected Laser Sintering (SLS) and Selected Laser Melting (SLM) are, just now, enabling ceramic based scaffolds without the need for a second sintering stage (Trombetta *et al.*, 2017).

Moreover, biomedical systems are already capable to print proteins and cells so current research interest mainly resides in the bioprinting of organs and tissues and bioprinting of hard tissues such as bone and tendons have received a special attention (Bonneau and Yi, 2017). Usually, the bioinks are composed by a hydrogel which contains cell or proteins in its matrix. Current 3D bioprinting technologies are based on: extrusion, stereolithography, inject and laser assisted (Derakhshanfar *et al.*, 2018). While extrusion based bioprinting is being widely studied, laser assisted bioprinting present interesting advantages: it is able to print volumes in the range of picolitres increasing the precision and high cell viability due to the last developments. For example, Blaser Assisted Laser Induced Forward Transfer (BA-LIFT) have extraordinary decreased the cell death due to the laser effects. Current studies are directed to the bioprint of hard tissues include CaP in the matrix of these hydrogels.

Properties and Applications

It was previously described that CaP is chemically similar with mammalian bones and teeth. In addition to their biocompatibility, one of their major features is their bioactivity. For these reasons, CaP are used in medicine for different medial applications related with hard tissue such as bone augmentation, dental fillings and periodontal treatments, implant fixations or vertebroplasty and kyphoplasty (Lewis, 2006).

There have been different developments in CaP ceramics and these advances have required the development of CaP-based materials with different characteristics and properties. For example, in 1950 self-setting abilities of CaP are discovered and in early 1980 CaP cements awake the interest of the biomaterials science community because of their suitable properties for bone repair, augmentation and regeneration but also because of their easy handling and injectability. Setting times, viscosity are important parameters for injectability (Ginebra, 2008) but also in the manufacture of 3D structures where the rheology studies had focused the attention of researchers.

Graham and van der Eb introduce a novel application in 1973 (Graham and van der Eb, 1973), when they demonstrated the capability of CaP to condense DNA and the transfection efficiency was increased with a relatively simple procedure. They are also suggested as drug delivery systems or for alternative tissue engineering purposes. CaP appear to be promising carriers of growth factors, bioactive peptides and various types of cells. In the 1990s, a multitude of papers about the use of CaP scaffolds as controlled drug delivering systems were published.

In other hand, first CaP coatings, films and layers appeared about 1975. Until that time, CaP had been limited to non-load bearing applications, since they are mechanically brittle. However, surface of any implant is always the first part to interact cells and surrounding tissues and, for this reason, the surface properties play a key role. Then CaP are suggested to be placed onto the surface of mechanically strong but bioinert or biotolerant materials (non bioactive), suitable for load bearing applications. CaP

improves biocompatibility and, consequently, prevents encapsulation, osteoconductivity, but mainly improves the bioactivity of the implants, facilitating their bonding to the bones. The objective of the coatings is to obtain the desired surface properties through changes in the surface of the material, but maintaining unchanged their bulk. The attempt to combine these requirements resulted in a discipline named surface engineering. Cohesion and adhesion of the coating to the substrate are key parameters studied in this discipline. Also fatigue, elastic modulus and hardness are important properties for the applications of coatings. Also the crystallinity, the solubility rate, the topography and the interaction with proteins and cells play important roles in the success of the coating (Surmenev *et al.*, 2014).

Nanosized CaP were introduced in 1994. Both a greater viability and a better proliferation of various types of cells have been detected on smaller crystals of CaP. These effects have been related with a higher surface-to-volume ratio, reactivity and biomimetic morphologies of the nanosized particles. Recent advances suggest that this is a natural selection, since the nanostructured materials promote specific interactions with proteins. For all these reasons, nano-sized and nanocrystal line forms of CaP have a great potential for bone repair and augmentation but also as drug delivery systems. Synthesis and development of nanomaterials, their singular properties and sophistication have revolutionized numerous research fields. They can develop more complex functions and be designed to mimic the physicochemical properties of natural materials (Surmenev *et al.*, 2014).

Finally, the great challenge that these materials face in their medical application is regeneration rather than tissue replacement (Li *et al.*, 2013). In the late 1990s applications of CaP in tissue engineering began. As previously described, CaP present suitable properties for the tissue engineering applications such as biocompatibility, biodegradability, bioactivity, high affinity for drugs, proteins and cells and possible osteoinductivity. Moreover, since the main goal in tissue engineering is to create tissues and organs *de novo* and cells need a support to be organized in a 3D disposition, one of the main trials has been the development of 3D porous structures which simulate the extracellular matrix. New developments to manufacture 3D porous structures soar. However, porosity decreases the mechanical resistance. This is an important parameter when implants are directed to regenerate bone tissue and it is a big challenge in the field. In the forefront, the bioprinting of hard tissues face two main challenges: the printing technology and curing methods after printing have been compatible with the viability of cells.

Final Remarks

Since humanity discovered the presence of CaP in living organisms, these compounds aroused great interest from the scientific community. The physico-chemical and biological properties of CaP have widely studied. They have been encouragingly postulated as bone grafts due to their similar chemical composition to bones, biocompatibility and bioactivity properties. While first bone grafts only pretended to substitute bone damaged or bone lost, the modern bone grafts pursue the bone regeneration by mimicking body's own self-repairing abilities. This new generation of bone grafts acts as temporal substrate for bone cells but they must biodegrade with the time to give the way to new bone tissue formed. Osteoinduction and biodegradation or bioresorption are new properties required. Also the obtention of 3D structures with interconnected macro and micro porosity are mandatory. CaP possess attractive biological properties in terms of biocompatibility, bioactivity, bioresorbability, and osteoinductivity. In addition, advances in other research fields such as, materials engineering (nanotechnology or 3D printing technologies), tissue engineering (bioprinting), surface engineering, and alternative applications such as drug delivery or gene therapy, have driven the research of CaP as biomaterials. For example, due to their ceramic nature, which confers brittleness, CaP were limited to non-load bearing applications. However, they have been also suggested as coatings to provide bioactivity over metallic implants for load-bearing applications. In other hand, CaP self-setting formulations offered the possibility to be easy handling, minimal invasion and capability to adopt required shapes. Also, CaP have been suggested as vehicles for drug delivery systems (antibiotics, anti-inflammatories, growth factors, etc.) and ADN or ARN transfection. In other hand, several polymer-ceramic composites have been developed and studied to decrease the brittleness of ceramics, provide bioactivity to the polymers and aid the controlled release of drugs. Finally, 3D printing technologies have revolutionized the manufacture of scaffolds and bone grafts. Last advances have proposed 3D printing of self-setting CaP formulations. The current interest is focused in the bioprinting of hard tissues which involves 3D printing of composite materials, usually hydrogel-CaP composite, and cells or proteins.

To conclude, CaP continue playing an important role in the research of medical devices for Biomedical Engineering.

Introduction

The ability of bones to self-heal and regenerate has been intensively studied since ancient times ([Hippocrates and Adams, 1939](#)). Indeed, bones and hard tissues including the cartilage and teeth are of key importance for the human life, in terms of mobility, manipulation, chewing, and thus it is today one of the most demanding issues in medicine. The bone physiological healing response is active toward a complete and effective regeneration only in case of small defects, while critical-size and load-bearing bony regions require the transplantation of bone substitutes. Given its importance, it was estimated that bone represents nowadays the second most common transplanted tissue after blood, with the iliac crest autologous graft being most used ([Shegarfi and Reikeras, 2009](#)).

Given the limited availability, risk of site morbidity and immune responses related to the use of autografts and allografts from donors, a great deal of research effort has been devoted in the last decades to the development of synthetic scaffolds, aiming to drive and sustain the bone regeneration process. A wide consensus is today consolidated toward the concept of “biomimetics”, that is the intrinsic ability of a synthetic material to closely reproduce the chemical composition, physical properties, and architecture of native tissues, with the purpose to create 3-D environments able to deliver signals stimulating cell chemotaxis and specific differentiation of autologous stem cells ([Tampieri et al., 2011](#)).

As the major component of bone tissue is a calcium phosphate, namely a ceramic material, the term *bioceramics* refers to the class of materials investigated for bone repair and regeneration. In the last decades, the research on regenerative bioceramics has greatly expanded, with the purpose to achieve the optimal composition, multi-scale structure, and mechanical performance.

In this respect, this chapter describes the main features requested for ceramic bone scaffolds and the most recent approaches to develop regenerative bioceramics, with particular respect to bioactive ceramic nanoparticles and their functionalization, 3-D porous ceramics and self-hardening injectable ceramic pastes and cements. Furthermore, the chapter explores recent advances in additive manufacturing techniques that, in spite of technological difficulties, are considered as a major approach to obtain implantable, personalized devices with organized and tailored porosity. Finally, the chapter gives an overview on some clinical results encouraging further research in the field.

Requirements for Regenerative Bioceramics: Physicochemical, Morphological, and Mechanical Aspects

The interaction of biomaterials with living tissues is driven by multiple factors acting in a synergistic fashion. Particularly, it is today well known that, in their adhesion to a foreign substrate, stem cells respond to environmental conditions dictated by the substrate composition, pH, nano-texture, multi-scale porosity, and mechanical behavior such as elasticity and toughness under physiological multi-modal loading.

The composition of a scaffold is important because it can induce specific cell response by biochemical recognition. Bone tissue composition includes about 70% of hydroxyapatite (HA) and 30% of collagen by weight ([Biltz and Pellegrino, 1969](#)). For this reason, calcium phosphates (CaPs) closely mimic the bone tissue and provide higher osteoblasts adherence and proliferation when compared to other materials ([Stevens et al., 2008](#)). A very high number of calcium phosphate bio-devices have been developed in the past decades, mainly for orthopedic, maxillofacial, and dental applications ([Thamaraiselvi and Rajeswari, 2003](#)). Hydroxyapatite, the most stable crystalline CaP at physiological pH, can be obtained by a multitude of synthesis approaches, particularly as ion-doped phases to improve the compositional mimicry with bone and enhance bioactivity/bioresorbability and, in turn, enhanced osteoconduction and osteoinduction ([Turnbull et al., 2018](#); [Wang and Yeung, 2017](#); [Gomes et al., 2018](#); [Basu and Basu, 2019](#); [Iafisco et al., 2018](#); [Shahrezaee et al., 2018](#)). The bioresorbability of calcium phosphates is greatly related to their microstructure and is enhanced if low temperature syntheses are used. On the other hand, high-temperature sintering processes may improve the mechanical performance of bioceramics, but limiting their bioresorbability ([Dorozhkin, 2010a](#); [Prakasam et al., 2015](#)). In general, the biological in vitro and in vivo performance of a scaffold designed for regenerative medicine are related to the composition, as when a biomaterial is implanted in living tissues a layer of water molecules rapidly forms on its surface, influencing the deposition of the subsequent layer of proteins, finally guiding the interaction of the scaffold with the surrounding cells ([Wilson et al., 2005](#); [Othman et al., 2018](#)).

Besides the composition, the nano- and micro-architecture of scaffolds is a critical factor in encouraging cell viability and promoting tissue ingrowth, as shown by previous studies reporting enhanced adhesion of cells to the scaffold by tailoring micro- and nano-features of the scaffold surface such as the surface area and roughness ([Wang and Yeung, 2017](#); [Meco and Lampe, 2018](#); [Ashworth et al., 2018](#); [Bružauskaitė et al., 2016](#)). Scaffold porosity must be precisely engineered to obtain features making cells migration and proliferation favorable. Despite a wide range of studies have been performed to investigate the best range of porosity for a bone scaffold, the precise tuning of pore size and shape still comes demanding. The mean pore size determines the

Fig. 1 Crystalline structure of Hydroxyapatite with examples of ionic substitutions.

surface area of the scaffold: among ceramic bodies presenting the same overall porosity extent, a decreased pore size reflects in an increased availability of scaffold ligands toward a more stable interaction with the surrounding cells with improved cell-scaffold anchoring and osteogenic effects (Rouahi *et al.*, 2006). However, a too small pore size can complicate the migration of cells into the scaffold. It was shown that scaffolds implanted in vivo with pore sizes close to 300 μm promote osteogenesis due to higher permeability and potential for vascularization, whereas smaller pore sizes are more favorable for chondrogenesis (Kuboki *et al.*, 2001; Walthers *et al.*, 2014). Therefore, the best compromise is to present a multi-scale porosity to cells, i.e., macro-pores allowing cell and osteon ingrowth in vivo, and micro-pores to encourage cell-scaffold ligand interactions. A key factor is the pore interconnection that is mandatory to improve the diffusion of oxygen and nutrients and outwards diffusion of waste products from the scaffold. Also, interconnected porosity favors the confluence of new bone tissue from the external to the inner parts of the scaffold and promotes vasculogenesis, i.e., the formation of a well-developed vascular network for blood circulation.

The porosity extent and pore architecture are strictly related to the scaffold mechanics. In fact, porosity supports osteointegration that gives mechanical stability while also having significant relevance on the final mechanical performance of the bone-scaffold construct. Such performance is relevant for the activity of bone cells: the transfer of dynamic, complex biomechanical forces by the macroscopic scale to the cell level activate mechano-regulatory effects involving complex biochemical reactions which are key in influencing bone tissue growth, cellular differentiation, and bone remodeling (Isaksson *et al.*, 2008). In the lack of bio-competent mechanical response, cells may be stimulated to detach from the substrate or to differentiate away from an osteogenic lineage toward an undesirable morphology (Boccaccio *et al.*, 2011). Thus, bone regeneration process is highly affected by the mechanical loading and the stress distribution along the scaffold, favoring or inhibiting the cell differentiation.

Based on these premises, the take-home message is that the ideal scaffold for bone regeneration should be provided with bone-mimicking composition and a multi-scale porous structure able to transfer the mechanical forces in a fashion similar as the natural bone. This is a major challenge for material scientists, considering the possible alteration of the desired phase composition due to the ceramic processing and, also, considering that the scaffold mechanical stiffness and porosity are directly conflicting other physical properties, with mechanical strength inversely related to increasing scaffold porosity (Chan and Leong, 2008).

Methods for Bioceramic Synthesis

Bioactive Nanoparticles: Imparting Biofunctionalities by Specific Ion Doping

Human hard tissues are basically composed of poorly crystalline carbonate-substituted nanosized apatites (CHA), with the exception of enamel, which has a high degree of crystallinity (Combes *et al.*, 2016; Dorozhkin, 2009; Gómez-Morales *et al.*, 2013; Iafisco *et al.*, 2014a; Rey *et al.*, 2007; Tampieri *et al.*, 2016). Biologic bone apatites are non-stoichiometric (Ca/P ratio less than 1.67) and calcium-deficient (i.e., they also show Ca vacancies) and incorporate ions substituting calcium, phosphorous and hydroxyl (i.e., Mg^{2+} , CO_3^{2-} , Sr^{2+} , Na^+ , K^+ , SiO_4^{4-}) in the crystal lattice, in very varying extent, depending on the state of the bone metabolism (see Fig. 1).

This is in contrast with the stoichiometric hydroxyapatite phase (i.e., $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), which is stable and poorly soluble at physiological conditions. Among heterovalent substituting ions in biological HA, carbonate (CO_3^{2-}) is the most abundant (2–8 wt% De Groot, 1983), and partially enters both in the phosphate (PO_4^{3-}) site (B-type CHA) and the OH^- site (A-type CHA) of the HA structure. Such substitution depends on the degree of bone maturation, where the newly formed bone contains prevalently B-type carbonation and the mature bone is mostly carbonated in A position (Boskey, 2006). B-type carbonated hydroxyapatites showed improved solubility, collagen deposition in vitro and reabsorption in vivo and enhanced activity for cell adhesion, when compared with stoichiometric HA and/or to A-type CHA (Landi *et al.*, 2008a; Boskey, 2006). Among other foreign ions present in the biologic apatite, magnesium (Mg^{2+}) has the marked property of increasing the nucleation kinetics of HA on collagen fibrils but, in the meantime, hampering crystal growth, thus generating nano-size HA nuclei, strongly enhancing the bioavailability of the mineral phase. In fact, magnesium is found in much higher concentrations in young and newly formed mineralized tissues and is considered

today as a fundamental element governing the first stages of bone formation (Bigi *et al.*, 1992). Trace elements present in the natural bone such as silicon are essential for healthy skeletal development in higher biological organisms (Pietak *et al.*, 2007), in particular for its role in the crosslinks between collagen and proteoglycans that stabilizes the new bone matrix and prevents enzymatic degradation (Carlisle, 1970). Strontium ions (Sr^{2+}) elicit great interest because it can regulate the activity of osteoblasts and osteoclasts by activating signaling pathways through a cation-sensing receptor (CaSR) present in both these cell lines (Takaoka *et al.*, 2010; Querido *et al.*, 2016; Marie *et al.*, 2001), thus helping to equilibrate the bone turnover. For this reason, the doping with Sr^{2+} ions elicits great interest to fabricate bioceramics able to promote bone healing in the presence of metabolic diseases such as osteoporosis (Cianferotti *et al.*, 2013; Fogelman and Blake, 2005). Interestingly, several ions and molecules can modulate bone remodeling by activating or inhibiting such CaSR, which may be considered a promising strategy for the treatment of bone diseases (Cianferotti *et al.*, 2015). A significant association has been also found between bone density and the intake of Mg, an essential micronutrient with a wide range of metabolic functions, including the maintenance of osteoporotic bone integrity (Castiglioni *et al.*, 2013).

In this context, the enhancement of the *in vivo* bioactivity and biodegradability of calcium phosphate phase was also investigated by the preparation of calcium phosphate nanoparticles (CaP NPs) by using a vast range of methods, including sol-gel, solution spray drying, hydrothermal process, precipitation techniques, solid-state reaction, and biomimetic deposition (Karimi *et al.*, 2016; Manuel *et al.*, 2004; Okada and Furuzono, 2012; Owens *et al.*, 2016). The use of biomimetic synthesis conditions (e.g., body-like synthesis temperature) helps to maintain a poorly developed and disordered nanocrystal structure allowing the entrapment of ions naturally present in the physiological environment into the structure of the mineral phase (Tampieri and Sprio, 2016; Bohner *et al.*, 2013; Iafisco and Degli Esposti, 2018). As a general rule of thumb, the ions of one element can extensively replace those of another in ionic crystals when their radii differ by no more than 15% and their charges by no more than ± 1 , provided that electrical neutrality is maintained (Goldschmidt, 1926). In general, substitution can be limited by poor structure flexibility and by the different electronegativities of the competing ions, which form bonds of different ionic behavior. Multiple ion doping has been also extensively explored. For example, the synthesis of HA powders co-substituted by silicon and other ions in anionic (carbonate) or cationic sites (magnesium) was carried out by neutralization of a calcium hydroxide suspension (calcium source) by an orthophosphoric acid solution (phosphate source) in aqueous environment, with the addition of suitable salts of the substituting ions (Sprio *et al.*, 2008; Iafisco *et al.*, 2014b). It was demonstrated that co-substitution is limited by the competition arising between ions attempting to occupy the same crystallographic site (Mg and Sr for Ca, for instance). Multiple doping was also used to investigate antibacterial ability, such as gallium or Zn, proving an effective antibacterial effect against some bacterial strains, without reducing the viability of human cells (Ballardini *et al.*, 2018; Sprio *et al.*, 2019).

CaP NPs are often developed as starting materials for the fabrication of 3-D scaffolds. However, several applications of CaP NPs as a bio-device include cell transfection, gene silencing, drug delivery, biomedical imaging (Epple *et al.*, 2010), and also for cardiac delivery of MicroRNAs (Mauro *et al.*, 2016). In this respect, functionalization processes to decorate the surface of HA or to induce specific crystallization pathways are widely explored.

Approaches for Biomimetic Functionalization of Bioceramics

Among bioceramics, synthetic hydroxyapatites exhibit excellent biological properties such as biocompatibility, bioactivity, lack of toxicity or inflammatory and immunologic responses, and also a relatively high bioresorbability (Degli Esposti *et al.*, 2018). These properties can be significantly enhanced by improving their biomimetism, that is, by preparing them with similar dimensions, morphology, surface, and chemical characteristics as for biological ones. In recent years, hydroxyapatites with different stoichiometry, size and morphology have been generated and the effects of varying synthesis conditions on stoichiometry, crystallinity and morphology have been investigated and elucidated (Dorozhkin, 2010b; Roveri *et al.*, 2008; Sadat-Shojai *et al.*, 2013).

The significant role of surface in biological phenomena such as protein adsorption and bone cell adhesion to implanted bioceramics has been put forward in the last years highlighting that the capability to tailor surface structure at the micro- and nanoscale level may boost the possibility to elicit specific responses from cells in addition to optimizing the *in vivo* response (Norton *et al.*, 2006). The surface properties of hydroxyapatite govern the affinity and the binding mechanisms between biological macromolecules (e.g., proteins) and the hydroxyapatite surface, which indirectly determines the interactions between bone cells and implanted biomaterials (see structural model in Fig. 2). The surface properties ultimately play a pivotal role in determining the success of bioceramics as bone implant and/or drug carrier (Lee *et al.*, 2014). Modifications of the surface properties can occur through the addition of new functional molecules or by a direct modification of the surface by physical techniques (e.g., photolithography). Roughness, surface charge, surface energy, wettability, microporosity, and crystallinity can be nowadays perfectly tailored by using several methodologies.

In general, surface modification of bioceramics based on hydroxyapatite by the addition of new molecules may be classified as physical or chemical functionalization. Direct immobilization or physical immobilization is the simplest way to impregnate molecules onto the hydroxyapatite surface. In this case, functional molecules are adsorbed via weak non-covalent interactions, such as electrostatic, van der Waals, hydrogen bonding, and/or hydrophobic interactions (Gómez-Morales *et al.*, 2013).

One of the most exploited methods for chemical (i.e., covalent) functionalization of bioceramics with bioactive molecules is the reaction of surface hydroxyl groups with substituted alkoxysilanes (Russo *et al.*, 2014). Silanol groups from hydrolyzed silicon alkoxides are able to condense with the hydroxyl groups of the orthophosphate scaffold, while the alkyl chain bears the functional group that can be exploited for further functionalization. Amine functional groups are extensively used for surface

Fig. 2 Proposed model of the apatite nanoparticle composed of a well-ordered apatite core covered by a non-apatitic hydrated layer composed of ionic species, including citrate, and structural water. TEM image shows this layered structure. From Delgado-López, J.M., Iafisco, M., Rodríguez, I., *et al.*, 2012. Crystallization of bioinspired citrate-functionalized nanoapatite with tailored carbonate content. *Acta Biomaterialia* 8, 3491–3499.

functionalization because they are quite versatile and particularly suited for condensation reaction to the corresponding amides; in this respect, (3-aminopropyl)triethoxysilane (APTES) is one of the most widely used reagents. The silanol groups at one end of hydrolyzed APTES can form a binding with OH groups exposed on the material surface, while its amine group can be exploited for further covalent derivatization with organic (bio)molecules.

Taking into account the biomimetic concept, the most promising methods for the design of optimized structural and surface features are those that take inspiration from the architecture of biological tissues to improve biological affinity of the bioceramics with other materials, such as, for instance, the immobilization of biological relevant molecules on the surface of bioceramics.

For example, it was shown that hydroxyapatite pre-coated with the biomimetic arginine-glycine-aspartic acid (Arg-Gly-Asp; RGD) peptides then over-coated with serums increased mesenchymal stem cell (MSC) attachment and spreading on HA, compared to either coating alone (Sawyer *et al.*, 2005). Interestingly, the added stimulatory effect of RGD and serum on MSCs was only observed when HA was coated with low concentrations of RGD. The authors suggested that at high densities, RGD changed the conformation of absorbed osteogenic proteins (e.g., fibronectin) such that the proteins did not engage or fully activate cell surface receptor.

Recently, citrate molecules strongly bound to the surface of bone apatites (1 molecule per every 2 nm²) have been identified by advanced solid-state NMR and proposed to be responsible for the inhibition of crystal thickening and also for the stabilization of nanocrystals within the collagen matrix (Hu *et al.*, 2010). NMR studies have revealed that citrate represents 5.5 wt% of the organic matrix of bone (Hu *et al.*, 2010). Due to its excellent chemical and biochemical properties, like its excellent Ca-complexing power and its bioavailability, citrate has been molecules for the preparation of synthetic hydroxyapatite nanoparticles that incorporated the molecules to their surfaces (Lopez-Macipe *et al.*, 1998). The strong effect of citrate on hydroxyapatite crystallization has been studied using complementary techniques such as X-ray diffraction (XRD) and synchrotron X-ray Wide Angle total scattering (WAXTS) (Delgado-López *et al.*, 2014), atomic force microscopy (AFM) (Delgado-López *et al.*, 2014; Jiang *et al.*, 2008), solid-state nuclear magnetic resonance (ssNMR) (Hu *et al.*, 2010), IR and Raman spectroscopy (Delgado-López *et al.*, 2012), and high resolution transmission electron microscopy (TEM/HRTEM) (Sakhno *et al.*, 2015).

These studies have proved that citrate plays a dual role in HA crystallization. First, citrate drives the growth of HA via an amorphous precursor, and second citrate induces a non-classical oriented aggregation of the nanocrystals (Chatzipanagis *et al.*, 2016; Delgado-López *et al.*, 2014; Iafisco *et al.*, 2015). Furthermore, during crystallization early HA nanocrystals undergo an oriented

Fig. 3 Schematic representation of the four main approaches to fabricate macroporous ceramics.

aggregation by attachment of the citrate-free (0 0 0 1) faces (Iafisco *et al.*, 2015). The consequence is that hydroxyapatite nanocrystals synthesized in presence of citrate usually are nanoplatelets 80–100 nm long, 30–50 nm wide, and 5–10 nm thick. Citrate-functionalized HA nanocrystals have excellent biocompatibility and colloidal stability and have been tested for drug delivery, imaging, coating of metallic prostheses, and many other applications (Di Mauro *et al.*, 2016; Miragoli *et al.*, 2018; Martínez-Casado *et al.*, 2015; Delgado-López *et al.*, 2013).

3-D Forming Technologies to Fabricate Scaffolds with Tailored Porosity and Mechanics

The ability of a scaffold to successfully regenerate a bone defect is greatly related to the combination of key properties including chemistry, morphology, pore size, microstructure, and mechanical performance (Bose *et al.*, 2013). In this respect, solid metal implants are characterized by very different mechanical properties if compared to the surrounding bone tissue, leading to local bone-implant mismatch and bone resorption, possibly inducing stress shielding effect (when a substantial difference between the Young's modulus of bone and implant occur Arifin *et al.*, 2014) or implant failure. In fact, it was demonstrated that insufficient load transfer from the implant to the surrounding bone may result in bone reabsorption with relative loosening of the prosthetic implant (Dujovne *et al.*, 1993). This concept can be related also to the mechanotransduction, that is, the process by which bone cells convert mechanical energy, including gravity, tension, compression, and shear stresses, into biochemical signals, to maintain adult bone health and homeostasis. Despite the knowledge about the precise molecular pathways underlying such mechanotransduction phenomena is still matter of intense research, it is clear that the mechanical performance of an implanted scaffold play a vital role toward the long-term successful bone-implant construct (Stroe *et al.*, 2013; Yavropoulou and Yovos, 2016).

Non-porous bioceramics exhibit high mechanical strength, but their clinical use is very limited because of the impossibility to induce bone ingrowth into such material and to achieve substantial osteointegration (Gauthier *et al.*, 1998), as shown, for example, in various cranioplasty procedures (Sprio *et al.*, 2016b). Hence, a great deal of research effort is being devoted in the development of porous bioceramics (Lew *et al.*, 2012). They can be made by a variety of methods, including partial sintering, sacrificial fugitives, replica templates and direct foaming (Turnbull *et al.*, 2018; see Fig. 3):

- (1) *Partial sintering* of bioceramic powders involves high-temperature sintering to control the diffusion or evaporation condensation of atoms induced by heat. In this case, the final porosity is the result of a thermal treatment adequately terminated before a full densification occurs. The features of the final structure are mainly influenced by the size of starting powders as well as the high-temperature treatment, which directly impact on the degree of interaction between grains, thus determining also the final mechanical strength of the structure (Ohji and Fukushima, 2012; Ersoy *et al.*, 2015).

- (2) *Sacrificial fugitives* can be mixed with ceramic raw powders as pore forming agents. These components are generally classified into synthetic organic matters (e.g., polymer beads, organic fibers, etc.), natural organics (potato starch, cellulose, cotton, etc.), metallic and inorganic matters (nickel, carbon, fly ash, glass particles, etc.) and liquid (water, gel, emulsions, etc.). The sintering process provokes the burning out of these additives and creates pores in the consolidated ceramic structure (Ohji and Fukushima, 2012). In this case, the critical step refers to the homogeneity of the dispersion of the fugitive with the ceramic powders (Landi *et al.*, 2008b).
- (3) *The replica technique* is a valuable approach to fabricate macroporous bioceramics with interconnected porosity and open cell walls. The process begins with the impregnation of a porous or cellular structure (e.g., the most frequently used template is porous polymeric sponge, such as polyurethane or cellulose (Tampieri *et al.*, 2001)) with ceramic slurries showing appropriate viscosity and fluidity in order to achieve a homogeneous ceramic layer over the sponge walls. Finally, the as-obtained ceramic-impregnated templates are adequately dried, thermally treated to decompose the organic sponges and sintered to achieve the complete densification of the structure.
- (4) *The direct foaming method* is an interesting template-free technique to obtain porous bioceramics, involving the inclusion of gases into ceramic slurry, followed by adequate stabilization. This process is particularly promising, especially due to the absence of organic phases to be eliminated during thermal consolidation, thus preventing possible structural damaging and penalization of the final mechanical properties (Stuart *et al.*, 2006). A key factor is the development of ceramic slurries with optimal rheological properties, so that they can be dried and physically stabilized upon pouring into pre-shaped containers, while maintaining shape, size, and distribution of the air bubbles that can be controlled to optimize overall porosity and mechanics for load bearing applications (Dapporto *et al.*, 2016).

In a different approach, the method adopts liquid phases to form a channel-like porosity, typical of cortical bone, by freeze-drying. The porous channels run from the bottom to the top of the samples during freezing/heating cycles, and the pores assume an anisotropic arrangement along the solidification plane with size and distribution controlled by changing the freezing temperature gradient through the process (Landi *et al.*, 2008b).

Injectable Bioceramic Pastes and Cements

When surgery on complex-shape bone defects or voids is requested, the implantation of 3-D massive scaffolds might not be the optimal solution, so that injectable and self-hardening biomaterials would be the elective candidate. Bone cements represent an injectable and self-hardening type of materials basically produced by mixing two phases, a powder and a liquid; upon mixing, the material is injected into the body, while the resulting paste progressively hardens into a solid mass (Ginebra *et al.*, 2012; Zhang *et al.*, 2014).

In the 1960s, a self-curing polymethylmethacrylate (PMMA) formulation was used for the first time to fix the femoral stem and the acetabular component in place (Charnley, 1960). However, given the significant drawbacks affecting the use of PMMA cements for bone regeneration (Vaishya *et al.*, 2013), calcium phosphate cements (CPCs) are investigated since the 1980s, when they were firstly developed by Brown and Chow (1983) and LeGeros and Cholley (1982). In these CaPs, the hardening reaction is based on the dissolution and precipitation of calcium phosphate phases into apatitic phases during hardening and it takes place at physiological temperature, avoiding heat peaks. The absence of exothermic phenomena allows also the incorporation of drugs and biological molecules, making them good candidates for drug delivery applications (Ginebra *et al.*, 2012). The ideal CPCs should be characterized by: easy preparation, full injectability, absence of phase separation during extrusion, in vivo hardening times to guarantee an adequate mechanical support, absence of disintegration upon immersion in physiological fluids, absence of shrinkage during setting, no toxicity, radio-opacity to follow the material during in vivo implantation.

In this respect, a lot of formulations have been developed with the aim to fulfill specific requirements for bone augmentation (Aral *et al.*, 2008), reinforcement of osteoporotic bones (Libicher *et al.*, 2006), fixation of metallic implants to weakened bone (Ooms *et al.*, 2003), spinal fractures and vertebroplasty (Lewis, 2006).

The CPCs leading to the formation of HA or calcium deficient HA (CD-HA) can be classified in two main categories, which are summarized in Fig. 4: (1) Single component, in which a single calcium phosphate compound, alpha-tricalcium phosphate (α -TCP), undergoes hydrolysis to CD-HA without varying the Ca/P ratio, according to (Ginebra *et al.*, 1999); (2) Multicomponent CPCs, in which two or more calcium phosphates, some more acidic and the other basic, set following an acid-base reaction. The basic component is normally tetracalcium phosphate (TTCP), and the most widely studied acidic reactants are either dicalcium phosphate anhydrous (DCPA) or dicalcium phosphate dihydrate (DCPD). The Ca/P ratio of the final HA depends on the ratio between TTCP and the acidic component (Ginebra *et al.*, 2012; O'Neill *et al.*, 2017).

Compared to acrylic bone cements or other polymeric injectable biomaterials, CPCs have the ability to form a direct bond with bone, and their osteoconductivity. In addition, they can be resorbable, with a resorption rate that depends on their composition and microstructural features. However, the main limitation of porous CPCs is mainly related to difficult injectability, poor mechanical performance, and brittleness, which has limited their applicability to bone anatomical sites not subjected to high mechanical loading. Several methods to reduce the phase separation of CaP materials during extrusion have been established, which include: increasing the liquid-to-powder ratio and injection rate, reducing plastic limit, and increasing the viscosity of the liquid component or the repulsive force between particles (Ginebra *et al.*, 2012; Zhang *et al.*, 2014). A significant challenge is the control of the rheology of concentrated suspensions or pastes (such as CPCs) as it is the result of

	Apatitic Cement		Brushitic Cement
	Single Component	Multiple Components	
Reactives	α -TCP	TTCP + DCPA/DCPD	β -TCP + MCPM/MCPA
Reaction	$3\alpha\text{-Ca}_3(\text{PO}_4)_2 + \text{H}_2\text{O} \rightarrow \text{Ca}_9(\text{HPO}_4)(\text{PO}_4)_5(\text{OH})$	$2\text{Ca}_4(\text{PO}_4)_2\text{O} + 2\text{CaHPO}_4 \rightarrow \text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$	$\beta\text{-Ca}_3(\text{PO}_4)_2 + \text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O} + 7\text{H}_2\text{O} \rightarrow 4\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$

Fig. 4 Classification of calcium phosphate cements, with examples of the most common formulations. From Ginebra, M.P., Canal, C., Espanol, M., Pastorino, D., Montufar, E.B., 2012. Calcium phosphate cements as drug delivery materials. *Advanced Drug Delivery Reviews* 64, 1090–1110.

complicate interactions among the powder particles and between the powder particles and the liquid component. Despite the huge amount of experiments reported in literature, the optimal tuning of the multitude of processing parameters is still a critical issue (O'Neill *et al.*, 2017).

An elective approach to prepare CPCs is based on the use of $\alpha\text{-Ca}_3(\text{PO}_4)_2$ as a metastable inorganic precursor for subsequent transformation into self-hardening hydroxyapatite cement in vivo. In this respect, cell-instructive properties can be implemented by doping with bioactive ions, commonly Sr^{2+} ions (Schumacher and Gelinsky, 2015), obtaining injectable devices able to locally release Sr^{2+} ions and modulate the activity of osteoblast and osteoclast cells. Furthermore, the addition of natural polymers to a CPC matrix is a recent strategy to improve several properties relevant for the cement processing, injectability and performance (Perez *et al.*, 2012). A recent study investigated a CPC formulation enriched with sodium alginate to improve the cement flowability during extrusion, mechanical properties and osteoinductive properties in vitro (Montesi *et al.*, 2017) and bone penetration in vivo, using a rabbit model (Sprio *et al.*, 2016a; see Fig. 5).

Fig. 5 Schematic representation of the alginate-containing CPC. After mixing of the powder and the liquid (a), a homogeneous paste was obtained and delivered by a syringe (b), leading to the rapid formation of apatitic crystal with a flaky to needle-like morphology (c). The paste was extruded into rabbit femoral condyle defects and hardening in vivo occurred. At 1 month after implantation (c), the bone cement (yellow arrows) revealed effective osteointegration and tight junctions with the surrounding lamellar bone tissue (d, inset scale bar: 1 μ m). From Sprio, S., Dapporto, M., Montesi, M., *et al.*, 2016a. Novel osteointegrative Sr-substituted apatitic cements enriched with alginate. *Materials* 9.

The future of CPCs relies on formulations including polymeric additives to achieve the injectability and setting behavior desired by clinicians, while providing the material with improved compression strength, reduced fragility, higher porosity, and bone-like viscoelasticity in the long term.

Additive Manufacturing of Bioceramic Scaffolds

The multi-scale features of a scaffold, i.e., pore size, shape, and interconnectivity, are difficult to be fully controlled with most of described approaches (Bose *et al.*, 2013). A claimed method to design and fabricate complex-shape structures is given by Additive Manufacturing (AM) that is a computer-aided process including slurry-based, powder-based, and bulk solid-based methods (Chen *et al.*, 2019). The general AM approach can be declined in a variety of 3-D manufacturing methods, namely vat polymerization, powder bed fusion, material extrusion, and binder jetting (Trombetta *et al.*, 2017; Ferrage *et al.*, 2016; see Fig. 6).

In particular, the *vat polymerization* (e.g., stereolithography) involves the polymerization of a photo-curable liquid polymer at the surface of a vat by a low-power ultraviolet (UV) light source; the *powder bed fusion* (e.g., laser sintering) employs a laser or electron beam to achieve selective thermal binding layer-by-layer of materials; the *material extrusion* deals with any process in which materials are deposited as continuous strands through a nozzle in an incremental layer-by-layer 3-D structure upon solidification of the extruded material, while the binder jetting selectively deposits one or more binding solutions from inkjets to induce the particles consolidation. In general, the adoption of 3-D printing technology may permit the control of scaffold shape and geometry but also a more precise tuning of fine features such as interconnected porosity, pore size, and distribution.

The possibility of manufacturing customized implants without shape limitations makes 3-D printing valuable for medical applications, especially for facial and reconstructive surgery (Hsieh *et al.*, 2017). Initially developed as a rapid prototyping method, 3-D printing technologies have been continuously evolving since the 1980s (Huang *et al.*, 2012). In the specific case of bioceramic scaffolds, the consolidation of the structure can be obtained by means of low-temperature or high-temperature post-processing treatments after the printing (Trombetta *et al.*, 2017). High-temperature sintered calcium phosphates, such as hydroxyapatite (HA), beta-tricalcium phosphate (β -TCP), have been employed to develop robocasted scaffolds for bone tissue engineering (Fu *et al.*, 2011; Franco *et al.*, 2010). However, the intrinsic low biodegradability of these high-temperature bioceramics represents a serious concern when considering its application in bone tissue engineering, where the scaffold must be degraded and progressively replaced by new bone. A possible approach to cope with such concern could be the development of self-setting ceramic ink that avoids the sintering step in the robocasted ceramic scaffolds. In this case, this process may allow the fabrication of biomimetic scaffolds, with chemical and microstructural features that are much closer to the mineral phase of bone than the high-temperature robocasted ceramics, and particularly with a higher resorption rate than sintered hydroxyapatite scaffolds. In addition, the low-temperature setting offers a valuable platform for the incorporation of biologically active molecules that can be used to promote

Fig. 6 Schematic depiction of the major technologies used in 3-D printing or composite calcium phosphate scaffolds for bone regeneration and drug delivery. From Trombetta, R., Inzana, J.A., Schwarz, E.M., Kates, S.L., Awad, H.A., 2017. 3-D printing of calcium phosphate ceramics for bone tissue engineering and drug delivery. *Annals of Biomedical Engineering* 45, 23–44.

osteinduction of the implant. This approach was successfully adopted by preparing self-setting formulations in some studies (Lode *et al.*, 2014; Maazouz *et al.*, 2014), even if more research is required to tune the rheology of the paste, thus improving the printing spatial resolution and the mechanical performance of the final scaffold (Xu *et al.*, 2017). In particular, the capability to extrude the material is a very critical aspect, especially if the reactivity of the particles modifies the rheological behavior over time, considerably reducing the possibility of continuous printing processes. One of the strategies to increase the injectability of calcium phosphate cements is the addition of a water-soluble polymer in the liquid phase, for example, gelatine (Montufar *et al.*, 2010) or sodium alginate (Sprio *et al.*, 2016a). The optimization of low-temperature self-hardening CPCs may broaden the applicability of this technique to potentially have in-hospital patient specific bone grafts, allowing surgeons to obtain ready-to-use bone grafts for a rapid treatment of emergency cases (Ginebra *et al.*, 2018).

Despite the various benefits and applications, a critical aspect of 3-D printing is represented by the intrinsically inanimate characterization of the printed scaffolds, as only the initial state is considered. In this respect, a more recent technique was introduced, called “4-D-Bioprinting”, where the additional dimension is represented by the time, intended as the responsiveness of the material, evolving overtime after implantation (Gao *et al.*, 2016).

Preclinical and Clinical Testing of Bioceramics

Bioceramics were extensively tested in the last decades for bone regeneration in both pre-clinical and clinical scenarios (Daculsi *et al.*, 2014). A large variety of commercial bioceramic bone substitutes have been developed; however, the major cruciality is represented by the difficult achievement of all the prerequisites for bone reconstruction. On the basis of the specific clinical scenario, bioceramics have to be mechanically competent, or injectable and self-hardening, or also shapeable. The results of animal experiments and clinical follow up studies showed that bioinert ceramics are characterized by high mechanical strength and minimal or no tissue reaction, confirming their cytocompatibility, but without any bonding with the bone. Conversely, bioglasses and glass ceramics exhibited nontoxicity, chemical bond to bone and osteoinductive property, while calcium phosphate ceramics exhibit nontoxicity, bioresorption ability and osteoinductive property (Thamaraiselvi and Rajeswari, 2003).

Porous HA scaffolds have been tested in different animal studies (Ciocca *et al.*, 2013; Woodard *et al.*, 2007) and clinical cases (Edwards and Ousterhout, 1987; Stefini *et al.*, 2015). In this latter cases, one of the most demanded clinical need in bone tissue

engineering refers to the regeneration of large skull defects (Sprio *et al.*, 2016b). A great deal of research effort has been devoted to the development of different biomaterials, including titanium, acrylic meshes as well as calcium phosphate-based bone grafts. Despite some interesting features in terms of shaping capability and mechanical performance, some drawbacks have been also reported, in terms of enhanced cold/heat conduction or hypersensitivity in contact with metals (Hanasono *et al.*, 2009; Lee *et al.*, 2009). In this respect, such inert materials also exhibit poor osteogenic and osteoconductivity, so that extensive penetration of the surrounding bone cells in the implant is severely compromised. In the last decades, hydroxyapatite-based porous scaffolds also came into clinical practice, basically due to possibility to customize the shape with the patient's defect, improved biocompatibility and biomimetic features. The hydrophilic character of HA favors cell attachment to the surface of the implanted scaffold, while the capability to produce HA scaffolds with open and interconnected multiscale porosity induced extensive bone ingrowth into the pores (Karageorgiou and Kaplan, 2005). Furthermore, histological examinations evidenced extensive bone penetration, particularly along the epidural surfaces (Boyde *et al.*, 1999). The improved biocompatibility in vivo of HA was also demonstrated by the absence of allergic reactions, infections, and morbidity during a two-years follow-up retrospective study (Staffa *et al.*, 2012). Indeed, nosocomial and post-operative infections are becoming a pandemic problem, due to the increasing bacterial resistance to antibiotic drugs, so that the use of implantable biomaterials effective to limit the biofilm formation is becoming imperative. Recent results report that calcium phosphates, particularly substituted HA phases, can be elective to elicit antimicrobial effect against a wide spectrum of infective strains, basing only on compositional and crystallinity features (Ballardini *et al.*, 2018; Sprio *et al.*, 2019).

Future Perspectives in the Fabrication of Regenerative Bioceramics

In the last decades, considerable advances were done in material science to replace inert, potentially toxic material with bioceramics permitting safer and improved long-term performance. Nevertheless, in spite of some relevant clinical success, several needs remain unmet so that the development of effective regenerative bioceramics is still an open challenge. A critical issue is surely the difficulty to overcome the so-called "death valley" from the lab to the patient bed and translate new biomaterials to clinics. From a scientific perspective, new fabrication approaches may enable a new generation of smart and multi-functional devices to reach the difficult goal to obtain porous materials showing bio-competent chemistry, structure and mechanics at the same time. In particular, new approaches for the thermal consolidation of bioceramics (e.g., conventional or pressureless spark plasma sintering, microwave sintering) can help to tune the nano and microstructural features of particles and grains, preventing their uncontrolled growth, toward adequate mechanical performance to promote long-term interaction between the scaffold and the surrounding load-bearing bone tissue. Furthermore, the research on CaP bone cements is highly active nowadays and promising to give new injectable biomaterials with enhanced bioactivity and mechanics, particularly for bone regions difficult to access by 3-D solid scaffolds and, also, to replace acrylic materials in spinal and neurosurgical applications. In this respect, new advances are envisaged also in additive manufacturing applied to self-hardening ceramic pastes, to overcome existing technological limitations and achieve 3-D scaffolds with highly complex structures that are impossible to be fabricated with conventional manufacturing methods.

Finally, the occurrence of post-op infections often hampers a positive clinical outcome. In this respect, the synthesis of bioceramics intrinsically provided with antibacterial and osteoinductive properties is an emerging research topic that promises to give findings, fundamental for clinical applications and substantially contributing to solve many of still unmet clinical needs.

Bioactive Glasses and Glass-Ceramics

Francesco Baino, Politecnico di Torino, Turin, Italy

Introduction: The Genesis of Bioactive Glasses and the Concept of Glass-Tissue Interfacial Bond

The concept of “bioactive” or “surface-active” glass was first introduced by Larry L. Hench at the University of Florida in the late 1960s when his research team developed the so-called 45S5 glass composition (45% SiO₂, 24.5% CaO, 24.5% Na₂O, and 6.0% P₂O₅ wt%), which was able to tightly bond to living bone (Hench *et al.*, 1971). The 45S5 glass was then tradenamed as Bioglass®, has been marketed for various dental and orthopedic applications, and has been used in hundreds of thousands of human patients (Hench, 2006). This has led to a considerable effort towards understanding the fundamental science that governs the physico-chemical, thermal and biomedical properties of bioactive glasses based on – or inspired by – the 45S5 formulation, so that novel glasses with enhanced biological efficacy could be designed (Table 1).

The chemical nature of the bond between the tissue and the material considerably enhances the interfacial adhesion of the implant; at the same time, the reactivity – strongly dependent on solubility – of bioactive materials is typically limited to their surface owing to the progressive “passivation” of the surface layer, which does not allow further degradation to progress rapidly to the bulk material. Therefore, a stable interface can be formed and maintained long enough to favor further cellular interactions in vivo and to induce the controlled growth of mature tissues.

Bioactive glasses can thus be intended as an ideal compromise between bio-inert materials (e.g., alumina and zirconia) and completely biodegradable materials such as α - or β -tricalcium phosphates, which undergo full dissolution upon exposure to physiological fluids and may be totally replaced with living tissues.

The mechanism of bioactivity and bone bonding of 45S5 glass has been first described by Hench and then confirmed by other authors (Hench, 1988; Greenspan, 1999). A hydroxycarbonate apatite (HCA) layer is generally believed to form on the surface of bioactive glasses upon contact with aqueous solutions (e.g., simulated body fluid (SBF) or physiological fluids) as a result of a sequence of reactions similar to the processes of conventional silicate glass corrosion:

- (1) Ionic exchange between Ca²⁺ and Na⁺ ions in the material and H⁺ and H₃O⁺ ions coming from the surrounding environment. Silanol bonds (Si–OH) are established on the surface of the glass. An increase of the solution pH is observed due to the release of alkaline ions and a silica gel layer forms on the surface of the glass. The chemical reaction can be described as follows:

This reaction occurs within a few minutes of exposure to SBF or body fluids. The surface layer is depleted of alkaline cations and is characterized by a net superficial negative charge. (PO₄)³⁻ ions, too, can be released into the surrounding fluids.

- (2) Breaking of O–Si–O bonds due to the high value of local pH determines, leading to the breaking of the silica network. Soluble silica is released in the form of Si(OH)₄ and the silanol groups are exposed on the surface of the glass in direct contact with the solution:

It has been demonstrated that the soluble silica released has a great impact on the proliferation of cells responsible for the formation of new bone in the adjacent area of the glass surface (Christodoulou *et al.*, 2005).

- (3) Silanol groups condensation and re-polymerization of an amorphous silica gel layer having poor content of Na⁺ and Ca²⁺ cations. The thickness of this layer typically varies between 1 and 2 μm . An increase in the proportion of bridging oxygens was observed during leaching. The surface of the material is characterized by a diffused micro-porosity, with an average pore size in the range of 3–5 nm and an effective surface area of up to 100 m²/g.

Table 1 Examples of bioactive silicate, borate and phosphate glass compositions (wt%)

Glass name	Production	SiO ₂	P ₂ O ₅	B ₂ O ₃	Na ₂ O	K ₂ O	CaO	MgO
45S5 Bioglass®	Melting	45	6	–	24.5	–	24.5	–
S53P4	Melting	53	4	–	23	–	20	–
13-93	Melting	53	4	–	6	12	20	5
Biosilicate®	Melting	48.5	4	–	23.75	–	23.75	–
CEL2	Melting	43.8	6.9	–	15.0	6.1	23.6	4.6
13-93B1	Melting	34.4	3.8	19.9	5.8	11.7	19.5	4.9
13-93B3	Melting	–	3.7	56.6	5.5	11.2	18.5	4.6
ICEL2	Melting	1.9	66.4	–	9.7	3.9	15.2	2.9
58S	Sol-gel	58.2	9.2	–	–	–	32.6	–
70S30C	Sol-gel	71.4	–	–	–	–	28.6	–

- (4) Ca^{2+} and $(\text{PO}_4)^{3-}$ ions, coming from both the material and the surrounding fluids, migrate through the silica gel layer towards the material surface. As a result, an amorphous calcium phosphate (ACP) layer forms on the top of the silica gel.
- (5) Hydroxyl and carbonate groups are incorporated from the solution while the process of dissolution of the glass continues starting from the surface. The ACP layer crystallizes to HCA. The resulting surface is very similar to the nano-crystalline mineral phase of the bone tissue from both compositional and structural viewpoints, and this allows the direct anchoring of the implant to the living tissue.

The five reaction stages described above may occur both *in vitro* and *in vivo*. If the glass is implanted in the body, the biological mechanism of bonding to bone involves adsorption of growth factors onto the surface HCA layer, followed by attachment, proliferation and differentiation of osteoprogenitor cells. Upon further degradation and conversion of the glass into HCA, osteoblasts can produce extracellular matrix composed of collagen microfibrils that mineralizes with nanocrystalline HCA on the surface of the implant.

45S5 glass was proved to be an excellent material and considered for long time as the “gold standard” bone substitute. However, it suffers from several drawbacks owing to (1) limited ability in sintering because it starts crystallizing before viscous flow takes place, (2) slow degradation kinetics which make it difficult to match the formation rate of new tissue, (3) abrupt pH variations in the biological microenvironment due to the increase in the concentration Na^+ and Ca^{2+} ions, especially in the short term when the release is faster (Jones, 2013). These are the reason why other glass compositions have been developed over the years (Table 1).

Bioactivity was demonstrated not only in silicate but also in borate and phosphate glass systems (Rahaman *et al.*, 2011). However, silicate glasses have always received higher attention in comparison to the other two classes of bioactive glasses mainly due to their higher chemical and thermal stability, which allows easy synthesis and processing of these glasses and provides flexibility to tailor their chemical compositions in order to achieve the desired properties. It has also been reported that the release of silica species from bioactive glasses in the range of 0.1 ppm to 100 ppm elicits a stimulatory effect on the osteoblast viability and promotes the expression of a range of genes involved in bone formation (Christodoulou *et al.*, 2005).

Several studies on the chemical dissolution of different melt-derived silicate glasses have led to the establishment of an empirical model that describes the relationship between glass composition and bioactivity (Ogino *et al.*, 1980). Specifically, silicate glasses with SiO_2 content varying between 45 and 52 wt% exhibited the highest bioactivity and were able to bond to both bone and soft collagenous tissues within 5–10 days. Melt-derived bioactive glasses and glass-ceramics containing 55–60 wt% of SiO_2 require a longer time to form a bond with bone and cannot bond to soft tissues. Glass compositions with more than 60 wt% of SiO_2 bond neither to bone nor to soft tissues, do not promote the formation of a surface layer of HCA and form a non-adherent fibrous interfacial capsule. It is worth pointing out that this composition-bioactivity relationship has been determined for glasses synthesized through melt-quenching route and may not be considered valid for sol-gel glasses: in fact, HCA was observed to form on the surface of gel-derived glasses with 90 mol% of SiO_2 after immersion in SBF (Li *et al.*, 1991). These differences in the bioactivity of melt-quenched and sol-gel glasses are due to the different surface chemistry of the two systems (presence of an inherent mesoporosity and high specific surface area in the materials synthesized by wet route) (Izquierdo-Barba and Vallet-Regi, 2015).

Production Processes and Types of Bioactive Glasses

Bioactive glasses can be produced by “conventional” melt-quenching route or sol-gel process. The melt-quenching route is conceptually easy but requires that the glass composition is properly designed in order to facilitate the melting process/casting into molds and to satisfy the reaction/bioactivity criteria in the biological fluids. On the other hand, the sol-gel method allows the expansion of the compositional range without compromising the system bioactivity; furthermore, it permits obtaining a high-purity product (no problems of contamination from the crucible material) and using a lower processing temperature (calcination temperatures are significantly lower than those required for melting).

Melt-Derived Bioactive Glasses

At present, the most-commonly used melt-derived bioactive glasses in clinics are 45S5, 13-93, and S53P4 (Table 1). In principle, the melting process of bioactive glasses is similar to that used for common soda-lime glasses for everyday applications. Melting of reagents (typically oxides and carbonates) is carried out at high temperatures (1200–1550°C) in an electrically-heated furnace. Process parameters (e.g., dwelling time at the melting temperature) is properly set in order to obtain a homogeneous and bubble-free melt. Platinum crucibles are the best choice to avoid contamination of the melt in biomedical applications; use of a cap is useful to limit the loss of boron, phosphorous and fluorine that tend to vaporize during high-temperature melting. Multiple melting steps may also be performed to reach ultra-high levels of homogeneity of the final product.

The available “dry” forming routes for (bioactive) glasses, according to the final product, include direct casting into molds, quenching into water to obtain a “frit” to further crush, or drawing into continuous fibers from a pre-form that was heated above the glass transition temperature (T_g).

After being ground and sieved, glass powders can also be heat-treated well above T_g in order to allow the sintering of particles into a porous architecture (scaffold) or to obtain a coating on a surface.

Crystallization is a critical aspect in view of the compositional range of melt-derived bioactive glasses since the thermal treatments, which are used for example to allow consolidation of the particles, could promote devitrification if carried out above the onset crystallization temperature (T_x). The presence of crystalline phases can significantly slower down the formation rate of the HCA layer on the material surface; nevertheless, it was reported that, even after full devitrification (100% of crystallinity), systems such as 45S5 Bioglass® still maintain a residual bioactivity (Peitl *et al.*, 1996; Arstila *et al.*, 2007).

Over the last years, considerable efforts have been addressed to developing melt-derived bioactive glasses that can undergo high-temperature thermal treatments without devitrification, in order to obtain, for example, good sinterability while maintaining good HCA-forming ability. In this regard, a successful example is the 13-93 glass composition which has a quite large sinterability window ($T_x - T_g$) and is approved for clinical use in Europe and USA (Rahaman *et al.*, 2017).

Bioactive silicate glasses

When Larry Hench started designing the formulation of a glass implant that could potentially bond to bone, he decided to use a quaternary silicate system containing both calcium and phosphorus, which are the main constituents of bone apatite. As a result, the 45S5 composition has a high Ca-to-P ratio and a relatively low melting temperature to allow easy casting into molds.

Addition of other oxides to the original 45S5 composition allowed further modulating the properties of bioactive glasses, such as dissolution rate and therapeutic effects via ion release (Hoppe *et al.*, 2011). It is impressive that, although more than 50 years have been passed since the discovery of 45S5 composition, intense research is still ongoing about this glass system and its medical applications in orthopedics, dentistry, and even soft tissue repair (Hench, 2006).

The main technological limitation of 45S5 glass concerns its small hot-working range: in fact, T_g and T_x of Bioglass® are very close, which limits the possibility of sintering by viscous flow without (partial) crystallization (Baino and Fiume, 2018) and leads to the decrease of apatite-forming capability. The glass S53P4, which is clinically used for maxillofacial surgery (Stoor *et al.*, 2010) and orbital floor repair (Peltola *et al.*, 2008) especially in Europe, also exhibits an easy tendency to crystallize upon heating (Massera *et al.*, 2012). More complex systems have a better stability against devitrification: for example, 13-93 has been proved to be bioactive and to have a larger sinterability window than Bioglass® due to the introduction of a higher amount of silica (53 wt%) together with K_2O and MgO , which are known to increase the hot-working range of glasses (Brink *et al.*, 1997). Fully amorphous 13-93 porous scaffolds mimicking the architectural and mechanical properties of cancellous bone were fabricated by the sponge replica method (Fu *et al.*, 2008), while robocasting was useful to produce strong 13-93 structures for load-bearing applications (cortical bone repair) (Liu *et al.*, 2013).

Very promising foam-like scaffolds, in terms of bone architectural biomimicry, bone-like mechanical properties and HCA-forming ability, were produced by applying the sponge replica method to melt-derived CEL2 glass powder (Vitale-Brovarone *et al.*, 2009a).

A very popular melt-derived bioactive glass in South America is Biosilicate®, which is clinically used not only for bone repair but also for the treatment of dentinal hypersensitivity, the replacement of middle ear small bones and the production of orbital implants for enucleated patients (Crovace *et al.*, 2016).

Bioactive borate glasses

Borate and borosilicate glasses are more reactive than silicate systems in contact with aqueous media such as body fluids, hence they are less durable and can convert faster to HCA than traditional SiO_2 -based bioactive materials. The bioactivity mechanism is conceptually similar to that of silicate glasses and involves the formation of a borate-rich gel layer instead of the silica gel. The rate of glass conversion into HCA can be modulated by tailoring the glass composition, thus varying the reaction time from hours to months (Huang *et al.*, 2006).

Borate-based glasses are appealing from a technological viewpoint as they have a lower T_g than silicate materials; glass transition can be tailored and increased by adding alkali and alkali-earth oxides in proper amounts. In general, borate glass products can be sintered more easily and in a more controlled way than silicate-based ones because of their ability to readily undergo viscous flow (Balasubramanian *et al.*, 2018).

Glasses in which SiO_2 was partially or totally replaced by B_2O_3 were found to be more reactive than their silicate counterparts (e.g., 45S5 Bioglass®) and to promote faster bone growth in vivo (Fu *et al.*, 2010). Particles of a SiO_2 -free borate glass were totally converted into HCA in less than four days; on the contrary, borosilicate glasses still maintained a silica-rich core after several weeks (Huang *et al.*, 2006). Bioactive borate and borosilicate glasses are also able to stimulate angiogenesis, which is key for promoting bone healing (Bi *et al.*, 2013).

An issue concerning the in vivo use of bioactive borate glasses is that high concentrations of $(BO_3)^{3-}$ ions is toxic to cells. Some in vitro biocompatibility tests have revealed that borate glasses can be cytotoxic if the tests are carried out in static conditions (Fu *et al.*, 2009). On the contrary, when the same tests were carried out in dynamic conditions or in vivo, no significant cytotoxic effect was detected due to the dilution of borate ions. In this regard, a threshold concentration for boron has been reported (0.65 mM) under which there was no toxic effect to cells and, thus, borate glass scaffolds could successfully support osteoblastic cell growth and differentiation. Safer conditions for cell culture/implantation in the body could be achieved by inducing HCA formation on the glass prior to cell seeding via pre-immersion in SBF (Fu *et al.*, 2009).

Having a larger sinterability window, borate glasses are more amenable to be processed than silicate ones and this property is very advantageous for obtaining high-quality sintered products. In this regard, Fu *et al.* (2009) used the sponge replica method to fabricate 13-93B1 glass scaffolds with 3D porous network mimicking the trabecular architecture of human bone (porosity 72 vol%, pore size ranging from 200 to 500 μm) and acceptable mechanical properties for osseous defect repair (compressive strength about 6.4 MPa). However, the same authors reported that the fast conversion of these borate scaffolds into

HCA was associated to the simultaneous decrement of mechanical properties during immersion in SBF (the compressive strength decreased to about 1 MPa within 1 month).

Recently, borate glasses have also been proposed in the form of micro-sized fibers for applications in wound dressing due to their pro-angiogenic properties associated to the release of boron and calcium ions (Balasubramanian *et al.*, 2018).

Bioactive and resorbable phosphate glasses

In the context of tissue healing, “restitutio ad integrum” is not possible if the biomaterial used to support the regenerative process does not completely dissolve once it has performed its function. In this regard, bioactive SiO₂-based glasses do not possess this ability – which means that residual silicate material will persist indefinitely in the body – unless they are synthesized in the form of nanoparticles (Vichery and Nedelec, 2016). However, fully-resorbable biomedical glasses can be obtained if P₂O₅ is used as a former oxide. Phosphate glasses are prone to congruently and totally dissolve over time in aqueous media, such as body fluids, and their dissolution rate can be varied from a few hours to some months by properly modifying the composition (Abou Neel *et al.*, 2009a). The low stability of phosphate glasses is due to the asymmetry of the structural tetrahedral unit [PO₄] and the easy hydration of P–O–P bond. The dissolution of these glasses is regulated by two interdependent stages: (1) surface hydration associated to Na⁺/H⁺ ion exchange and (2) rupture of the phosphate network due to breakage of P–O–P bonds in the hydrated layer. Metal oxides, such as TiO₂ (Abou Neel and Knowles, 2008), CuO (Abou Neel *et al.*, 2005) or Fe₂O₃ (Patel and Knowles, 2006), can be added to the composition in order to modulate (typically decrease) the dissolution kinetics of phosphate systems.

Being resorbable, phosphate glasses can be used as inorganic temporary platforms for the controlled release of biologically-active and therapeutic ions (Lakhkar *et al.*, 2013). In this regard, a number of antibacterial elements such as silver, copper, zinc and gallium were incorporated in the phosphate glass network and gradually released during the glass dissolution. It is worth pointing out that the ion release profile is much more linear in phosphate glasses compared to partially-resorbable silicate systems (Franks *et al.*, 2000). Phosphate glasses can also be drawn into fibers due to their relatively low T_g: under this form, they have been proposed for soft tissue engineering applications such as nerve (Vitale-Brovarone *et al.*, 2012) and muscle regeneration (Shah *et al.*, 2005), where the implantation of a tissue-like fibrous construct is key to guide cell growth.

Phosphate glasses have also been proposed for the fabrication of resorbable scaffolds for bone tissue engineering. For example, the composition of the silicate glass CEL2 was modified to obtain a phosphate glass named ICEL2 (Table 1), in which the molar percentages of the former oxides P₂O₅ and SiO₂ were inverted (Leonardi *et al.*, 2010). This phosphate glass showed a high tendency to dissolve in vitro when soaked in aqueous media like distilled water, SBF or TRIS (up to 75% of mass was lost over immersion for 4 months). Apart from being resorbable, ICEL2-derived porous glass-ceramic scaffolds produced by sponge replication (Vitale-Brovarone *et al.*, 2011) or polyethylene burn-off (Bretcanu *et al.*, 2014) also exhibited apatite-forming properties: in fact, small HCA agglomerates were observed to form on the scaffold struts in vitro in spite of the progressive dissolution of the material, which promoted stem cells to attach and differentiate into osteoblasts.

Phosphate glasses were also proposed as carriers for the local release of strontium, which is known to have anti-resorptive effects on bone tissue, thereby being effective in the treatment of osteoporosis (Peng *et al.*, 2009). In fact, the human body absorbs strontium in bones as if it is calcium due to the similarities between strontium and calcium ions. It was also reported that the replacement of Na₂O with SrO (up to 5 mol%) can significantly increase the dissolution rate of the phosphate glass, along with glass density and glass transition temperature (Abou Neel *et al.*, 2009b). This was due to the fact that SrO generates modifications in the glass network, increasing the number of Q¹ and Q³ units and decreasing the Q² ones. The increased dissolution rate produces the proportional increase in the release of Na⁺, Ca²⁺ and phosphate anions (e.g., (PO₄)³⁻) in the solution. On the contrary, the concentration of Sr²⁺ ions is proportional to the concentration of SrO in the glass and not to the dissolution rate. The control of the dissolution rate is useful to limit the change of pH in the solution (physiological value about 7.4) since a too fast or too large variation in the pH might be toxic for cells.

Sol-Gel Bioactive Glasses and Hierarchical Materials

While melt-derived silicate glasses cannot be bioactive if SiO₂ exceeds 60 wt%, glasses produced by sol-gel process still retain an excellent apatite-forming ability in spite of having a silica content up to 90 mol% (Li *et al.*, 1991). The exceptional bioactivity of these glasses relies on their inherent nano-texture associated to a high specific surface area (typically well above 50 m²/g), which governs the dissolution mechanism and leads to a significantly faster ion exchange with body fluids in comparison to melt-derived systems with analogous composition (specific surface area less than 0.5 m²/g) (Izquierdo-Barba and Vallet-Regi, 2015).

The sol-gel process is a chemistry-based (or “wet”) synthesis route in which the polymerization reaction of a solution containing precursors of the metal oxides leads to the gelation of the sol at room temperature. Biomedical sol-gel glasses are typically produced by hydrolysis and poly-condensation of alkoxyde precursors (e.g., tetraethyl orthosilicate (TEOS) or tetramethyl orthosilicate (TMOS)) followed by aging and drying at room temperature (Baino *et al.*, 2018). The oxide composition of sol-gel glasses is typically simpler as compared to melt-derived ones as the addition of high amounts of modifiers (e.g., Na₂O), needed to lower the melting temperature and facilitate glass processing, can be avoided in this case.

The sol-gel process can be summarized in five sequential stages (Hench and West, 1990). During step 1 (mixing), reagents are mixed together at room temperature to induce the formation of covalent bonds between the elements. Hydrolysis and poly-condensation occur simultaneously until homogenization of the solution is achieved. The step 2 (gelation) is associated to an

increase of viscosity due to the formation of a 3D interconnected network. The step 3 (aging) leads to a decrease of porosity as well as a remarkable improvement of mechanical strength. The liquid phase (alcohols) is removed during the step 4 (drying), which can be performed at a moderately high temperature (typically less than 200°C), and the obtained dry gel is finally stabilized by thermal treatment above 600°C (step 5).

Sol-gel glasses exhibit an typical nanoporous texture (mean pore size within 10–30 nm) which inherently derives from the synthesis process (Jones *et al.*, 2006). Smaller nanopores (typically 2–20 nm) with a well-defined symmetry and ordered arrangement could be obtained by incorporating supramolecular chemistry in the sol-gel process, leading to the advent of the so-called “ordered mesoporous materials”. For this purpose, surfactants are used to build micelles (above a critical concentration) due to the hydrophilic-hydrophobic features of those molecules, around which the silicate glass network can self-organize. In 1992, surfactant-templated pure amorphous SiO₂ was first synthesized and applied as a molecular sieve by researchers of the Mobil Oil Corporation (Kresge *et al.*, 1992) and, a decade later, Vallet-Regi *et al.* (2001) pioneered the biomedical use of these ordered mesoporous microspheres as a drug delivery system since small biomolecules could be hosted in the mesopores.

Interestingly, it was observed that mesoporous silica could promote the nucleation of HCA when soaked in SBF (Izquierdo-Barba *et al.*, 2005). This is in apparent contrast with the bioactivity mechanism suggested by Hench (1988), since there are no cations that can be released from the amorphous silica network and exchanged with ions from the solution to activate the apatite-forming mechanism. The bioactivity of mesoporous SiO₂ is still under debate but a partial explanation of the experimental evidence can be attributed to the role played by the unique textural properties of mesoporous materials: in fact, the ultrahigh specific surface area (well above 100 m²/g) seems to govern the material reactivity in aqueous media more crucially than the composition (Izquierdo-Barba and Vallet-Regi, 2015).

Hierarchical systems comprising a coating of pure-silica mesoporous microspheres (e.g., SBA-15, MCM-41) deposited onto the struts of bioactive glass-ceramic macroporous foams (large pore size within 50–500 µm) were developed as multifunctional implants for the simultaneous treatment of infections (via the controlled release of drugs from the mesopores) and acceleration of bone regeneration (via the glass bioactivity and bone growth inside the macropores) (Cauda *et al.*, 2008, Vitale-Brovarone *et al.*, 2009b).

Mesoporous bioactive glasses (MBGs), produced by incorporating additional oxides in the silica network, have been the topic of intense research over the last years. MBGs are typically more bioactive than melt-derived and “conventional” sol-gel-derived glasses due to the ultrahigh specific surface area which accelerates the ion-exchange reaction between glass and biological fluids (Wu and Chang, 2012).

MBGs were extensively proposed as highly-versatile platforms for the controlled release of both drugs and small amounts of metallic cations eliciting a therapeutic effect (Wu and Chang, 2014, Kargozar *et al.*, 2018a).

The fabrication of hierarchical MBG scaffolds exhibiting macro-mesoscale porosities is a difficult task due to two main reasons: (1) mesoporous materials are highly brittle due to the inherent mesoporosity and (2) the temperatures used to process MBGs cannot be increased too much (typically within 500–700°C) in order to preserve the mesoporous texture, thereby resulting in suboptimal densification. Co-templating strategies combining sponge replication (formation of large macropores) with surfactant-assisted sol-gel process (formation of mesopores) allowed fabricating scaffolds with appealing hierarchical porous structure but poor mechanical properties (compressive strength within 50–300 kPa (Wu *et al.*, 2010) versus 2–12 MPa for cancellous bone). Stronger hierarchical MBG scaffolds (compressive strength up to 16 MPa) having a grid-like structure of macro-sized channels and small mesopores on the struts were recently fabricated by applying additive manufacturing technologies, such as 3D printing (Zhang *et al.*, 2014).

Biological Role of Doping Elements

The exceptional versatility of bioactive glasses in term of physico-chemical and biological properties greatly relies on their composition, which can be finely designed and tailored to achieve the desired effect (e.g., fast resorption, quick HCA-forming kinetics). For instance, it was widely shown that the addition of monovalent and bivalent modifiers (e.g., K₂O, Na₂O, CaO, and MgO) is useful to decrease the thermal and chemical stability of the glass, resulting in an increase of the HCA-formation ability in silicate glasses (Brink *et al.*, 1997) and the resorption kinetics in phosphate glasses (Abou Neel *et al.*, 2009a). Furthermore, small amounts of metallic elements can be embedded in the glass composition so that, once released, can elicit an appropriate therapeutic effect at the implantation site (Kargozar *et al.*, 2018b). A summary of the biological effects elicited by the ionic species released from bioactive glasses is reported in Table 2.

Although the research field on ion-driven therapies is very challenging and potentially offers unique advantages – e.g., the use (and abuse) of antibiotics can be replaced by the controlled release of antibacterial cations, thus overcoming the problem of bacterial resistance (Kargozar *et al.*, 2018a) –, there are some issues suggesting caution in applying ion-releasing materials in clinics. In fact, some ions can be toxic to healthy cells even if released at low concentrations and their long-term effects *in vivo* still are partially unknown. A typical case is represented by Co²⁺ ions, which have been incorporated in bioactive glasses to promote angiogenesis (Kargozar *et al.*, 2017a; Wu *et al.*, 2011) but, concurrently, may interfere with cell metabolism and play a role in carcinogenesis and tumor growth (Littmann *et al.*, 2018).

Bioactive Glass-Based Products and Clinical Applications

Bioactive glasses, given their physical properties, stiffness and HCA-forming ability *in vitro* and *in vivo*, have been traditionally proposed for applications in contact with bone in orthopedics and dentistry (Tables 3 and 4).

Table 2 Biological role of the ionic dissolution products released from bioactive glasses

Therapeutic ion	Biological effects	Mechanism of action
Monovalent	Silver (Ag^+)	Antibacterial activity • Block of the respiration and electron transfer as well as collapse of the proton motive force in bacteria • Leakage of massive proton through the bacteria cell membrane
	Lithium (Li^+)	Osteogenesis • Activation of Wnt/Catenin signaling pathway • Stimulation of Col1, Runx2, ALP, and bone sialoprotein
	Fluoride (F^-)	Osteogenesis • Promotion of Akt and GSK3β phosphorylation and activation of the canonical Wnt/β-catenin signaling pathway • Stimulation of the expression of bone differentiation markers of COL1A1, ALP, and osteonectin
Divalent	Calcium (Ca^{2+})	Osteogenesis • Promotion of SMAD signaling pathway Angiogenesis • Increase of the expression of genes involved in angiogenesis including PDGF, EGF, IGF-I, bFGF, and VEGF • Induction of EC proliferation
	Strontium (Sr^{2+})	Osteogenesis • Activation of Wnt/Catenin signaling pathway • Up-regulation of genes expression of Runx-2, BMP-2, OCN, OPN, BSP, and Col1, ALP activity and matrix mineralization • Enhancement of the attachment, proliferation, and differentiation of osteoblastic cells • Reduction of osteoclast activity
	Manganese (Mn^{2+})	Osteogenesis • Up-regulation of Runx-2 and OPN
	Magnesium (Mg^{2+})	Antibacterial activity • Generation of ROS and inhibition of bacteria germination
		Osteogenesis • Activation of Notch1 signaling pathway
		Angiogenesis • Over-expression of COL10A1 gene
	Zinc (Zn^{2+})	Osteogenesis • Stimulation of PKC/MAPK signaling pathways
		Antibacterial activity • Enhancement of ROS production and damage to DNA, RNA and proteins • Destabilization of bacterial membranes
	Copper (Cu^{2+})	Anti-inflammatory activity • Decrease of the expression of TNF-α, IL-1β, and VCAM by inhibition of NF-κB activation via A20 and PPAR-α pathways
		Osteogenesis • Activation of bone metabolism via the action as a cofactor for lysyl oxidase • Inhibition of bone resorption through the action as a cofactor for superoxide dismutase
		Angiogenesis • Stabilization of nuclear HIF-1α simulating hypoxia, thereby activating proangiogenic factors VEGF, bFGF, TNF-α, and IL-1
Trivalent	Cobalt (Co^{2+})	Antibacterial activity • Attachment to the bacteria plasma membrane, causing lethal changes in the cell membrane such as disruption of membrane integrity inevitably
		Angiogenesis • Induction of HIF and thereby up-regulation of angiogenic factors VEGF and bFGF
	Cerium (Ce^{3+})	Osteogenesis • Activation of TGF-β/BMP and Smad1/5/8 signaling pathway and thereby up-regulation of genes of Runx 2, Col 1, BMP2, ALP, and OCN
	Gallium (Ga^{3+})	Antibacterial activity • Increase of the levels of ROS in the cerium-incubated bacteria cells, resulting in DNA, RNA, and protein damages
		Osteogenesis • Inhibition of the differentiation and resorbing activity of osteoclasts
	Boron (as BO_3^{3-} in biofluids)	Antibacterial activity • Inhibition of essential biological reactions in bacteria
Tetravalent	Silicon (as SiO_4^{4-} in biofluids)	Osteogenesis • Activation of MAPK signal pathway
		Angiogenesis • Up-regulation of VEGF and TGF-β1 genes
	Iron (Fe^{3+})	Osteogenesis • Activation of MAPK signal pathway
		Angiogenesis • Up-regulation of Runx2, ALP, and BMP2 genes
	Europium (Eu^{3+})	Angiogenesis • Overexpression of angiogenic genes of CD31, MMP9, VEGFR1/2, and PDGFRα/b
Pentavalent	Phosphorus (as PO_4^{3-} in biofluids)	Osteogenesis • Activation of BMP2 signaling pathway
	Niobium (Nb^{5+})	Angiogenesis • Induction of endothelial cell (EC) homing, cell polarization, migration
Pentavalent	Phosphorus (as PO_4^{3-} in biofluids)	Osteogenesis • Stimulation of the expression of matrix gla protein (MGP)
	Niobium (Nb^{5+})	Angiogenesis • Stimulation of pro-angiogenic FOXC2, osteopontin, and VEGFa • Enhancement of VEGF secretion

Table 3 Chronological development of bioactive glass products in medicine

Year	Achievement/application
1969	Invention of the 45S5 glass composition (45S5 Bioglass®) by Larry Hench
1977	Treatment of ear diseases by using Ceravital® glass-ceramics (replacement of middle ear small bones)
1978	Investigation of bioactive glass biocompatibility in the eye (cornea)
1985	Approval by Food and Drug Administration (FDA) in the USA of the first 45S5 Bioglass® implant (MEP®) for middle ear small bone replacement
1987	Treatment of liver cancer by using insoluble radioactive glasses
1988	Clinical use of the 45S5 Bioglass®-based Endosseous Ridge Maintenance Implant (ERMI) in human patients
1993	FDA approval of PerioGlas (45S5 Bioglass® particulate) for bone and dental repair
1998	First use of bioactive glasses in peripheral nerve repair
1999	FDA approval of radioactive glasses (TheraSphere®) for cancer treatment
2000	First use of bioactive glasses in wound healing
2002	FDA approval of Medpor®-Plus™ (polyethylene/45S5 Bioglass® porous orbital implant) for use in enucleated patients.
2003	Introduction of Zn-containing antibacterial bone/dental cements
2004	First use of bioactive glasses in lung tissue engineering
2004	Advent of mesoporous bioactive glass (MBG) as a drug delivery system
2005	First use of bioactive glasses in skeletal muscle and ligament repair
2005	First use of bioactive glasses in the treatment of gastrointestinal ulcers
2010	First use of bioactive glasses in cardiac tissue engineering
2011	Commercialization of a cotton-candy borate bioactive glass for wound healing in veterinarian medicine.
2012	First use of bioactive glasses in embolization of uterine fibroids
2012	First use of bioactive glasses in spinal cord repair
2018	First use of radioactive glasses (TheraSphere®) in patients with metastatic colorectal carcinoma of the liver

Table 4 Examples of bioactive glass products available on the market

Glass name or system	Commercial products and notes	Manufacturer
45S5	NovaBone® Putty and NovaBone® Dental Putty: moldable glass-based paste injectable into the bone/dental defect site by a syringe NovaBone® particulate (90–710 µm) for orthopedics NovaBone® Morsels (porous granulate) for bone repair PerioGlas® particulate (90–710 µm) for repairing jaw bone defects NovaBone® porous blocks for bone repair Biogran® particulate (300–360 µm) for bone repair NovaMin® particulate and BioMin for tooth enamel remineralization and dentinal hypersensitivity prevention	Novabone (USA); Mo-Sci Corp. (USA); Biomet 3i (USA); BioMin Technologies (UK)
45S5 + polyethylene	Porous composite orbital implant (Medpor-Plus™) for enucleation	Porex Surgical Inc (USA)
S53P4	Particulate for maxillofacial repair and custom-made monolithic plates for the repair of orbital floor fractures (BoneAlive®)	Abmin Technologies Ltd/Vivoxid (Finland); Mo-Sci Corp. (USA)
13-93	Cast monolithic implants, quenched frit, rods, fibers, disks, granules and micro-sized powders for bone repair	Mo-Sci Corp. (USA)
13-93B3	Cotton-candy fibrous scaffolds (DermaFuse™/Mirragen™) for wound healing	Mo-Sci Corp. (USA), Avalon Medical (USA)
70S30C	Sol-gel powder for bone repair	MedCell (UK)
Y ₂ O ₃ -Al ₂ O ₃ -SiO ₂ glass	Insoluble microspheres (TheraSphere®) for the treatment of liver cancer by embolization combined with local radiotherapy	BTG International Ltd (USA)

In the last decades, bone repair has become a major clinical and socioeconomic need due to the demographics associated with aging populations throughout the world (Clegg *et al.*, 2013); therefore, the availability of bioactive materials able to regenerate bone avoiding tissue transplantation is dramatically attractive.

The first bioactive glass product used in clinics dates back to 1980s, when melt-derived small blocks of 45S5 glass were implanted in the middle ear of deaf patients to recover sound conduction (Merwin, 1986). In the same years, 45S5 glass conical implants were also experimented as artificial dental roots in humans (Stanley *et al.*, 1997). Both products, albeit providing quite successful results from a clinical viewpoint, underwent progressive disuse as surgeons prefer to cut or shape the implant intraoperatively to match better the patient's anatomy, which is impossible with rigid pre-formed implants. At present, bioactive glasses are mainly used in the form of particles, granules or injectable putties that can be easily pressed into the bone site of concern: common applications of biomedical glasses include repair of traumatic or congenital osseous defects, bone

reconstruction following bone cancer removal, vertebral fusion, treatment of spinal osteomyelitis, tooth enamel remineralization, and prevention of dentinal hypersensitivity (Jones *et al.*, 2016). Glass-ceramics are of particular interest in dentistry for use in both dental root/alveolar bone surgery (if bioactive) and restorative/esthetic applications (if inert) (Montazerian and Zanutto, 2017).

Bioactive glass powder is often used as a raw material to fabricate three-dimensional (3D) scaffolds with an interconnected network of macropores mimicking the trabecular architecture of cancellous bone (Baino *et al.*, 2019a). Scaffolds are typically produced either by using a sacrificial material/template that acts as a pore-forming agent (e.g., open-cell polymeric sponge, plant-derived porous structures, starch and polyethylene grains), or by implementing additive manufacturing techniques (e.g., robocasting). Other strategies to obtain bioactive glass scaffolds include the freezing of glass particle suspensions and the foaming of a sol followed by thermal consolidation. Very innovatively, some researchers have tried applying sustainable approaches to the synthesis of bioactive glass scaffolds using “eco-friendly” raw materials. In this regard, natural marine sponges (Boccardi *et al.*, 2016) or stale bread (Fiume *et al.*, 2019) were proven to be inexpensive and suitable templates to produce bioactive glass foams mimicking the pore-strut architecture of cancellous bone.

Bioactive glasses are generally unsuitable for load-bearing applications due to their relatively poor mechanical properties (high brittleness, low bending strength, low fracture toughness); however, they can be applied as surface coatings on strong/tough implants to combine the adequate mechanical properties of the substrate with the high bioactivity of the glass, along with – in some cases – additional extra-functionalities like antibacterial properties and/or drug release (Baino and Verné, 2017). Research on this topic is still ongoing as there are some open challenges from a technological viewpoint; one of the most crucial is that the consolidation of bioactive glass coatings on metallic prostheses requires high-temperature sintering of the glass layer, with the associated risk of metal oxidation and glass/metal thermal expansion coefficient mismatch.

Bioactive glass fibers can be obtained by conventional drawing from a preform or even electrospinning to produce porous mats (Hong *et al.*, 2010). Furthermore, glass micro- or nano-sized particles can be incorporated in soft polymeric matrices to fabricate bioactive composites, that are very useful for interfacial hard/soft tissue engineering applications (Kargozar *et al.*, 2018c).

Recently, bioactive glasses have also been experimented in some novel applications in contact with soft tissues with very promising results (Table 3). Hench's 45S5 Bioglass® was reported to promote angiogenesis both in vitro and in vivo (rat model) (Gerhardt *et al.*, 2011). This property is peculiar of other glass compositions, too, such as 13-93B3 glass that was proved to be highly-effective in accelerating wound healing in both animals and humans (Wray, 2011). 13-93B3 glass resorbable fibers, which mimic the microstructure of a fibrin clot, have a high content of calcium that favors the migration of epidermal cells and, therefore, can promote the regeneration of skin even in diabetic patients for whom conventional treatment with drugs is unsuccessful. Angiogenesis can be further enhanced if this glass is doped with copper, as demonstrated in a rat subcutaneous model (Bi *et al.*, 2013). Application of these materials is currently approved for use in veterinary medicine only.

Commercial products comprising Ag-doped resorbable phosphate glass embedded in polymeric matrices are also used in clinics for preventing and combatting infections in wound dressing applications due to the sustained release of Ag⁺ ions.

The pro-angiogenic ability of bioactive glasses is also helpful in ophthalmology: in fact, 45S5 Bioglass®-coated porous polyethylene orbital implants, which replace the ocular globe in enucleated patients, could be invaded by vascularized connective tissue (fibrovascularization) more rapidly compared to the glass-free porous polymer (Baino *et al.*, 2019b).

Some special types of insoluble radioactive glasses are used for the treatment of liver cancer (Day, 2012). In a typical treatment, Y₂O₃-Al₂O₃-SiO₂ glass microspheres (mean particle diameter 25 or 30 μm, about 50 mol% of Y₂O₃ in the composition) are injected into the patient's bloodstream to lodge in the capillary bed of the liver, which is a highly-vascularized organ. Before arterial infusion, the glass beads are exposed to neutrons to create ⁹⁰Y, a radioisotope that has a short half-life (64 h) and decays to stable ⁹⁰Zr through emitting β-rays. As a result, a localized dosage of up to 15,000 rad can be locally delivered to kill cancer cells, with high benefits to the patient (3000 rad is the maximum dosage allowed under external radiotherapy). Apart from being used in the treatment of hepatocellular carcinoma for many years, radioactive glass microspheres have recently shown promise to combat kidney cancer and metastatic liver cancer in other organs, too.

Magnetite-containing melt-derived bioactive glasses as well as MBGs have also been proposed for the treatment of bone cancer via hyperthermia (Kargozar *et al.*, 2019).

Some examples of clinically-approved products based on bioactive glasses are reported in Table 4. Furthermore, there are a number of emerging applications in contact with non-calcified tissues and soft organs (Table 3) that have not reached yet clearance for clinical use, including cardiac tissue regeneration, artificial lungs, epithelial restitution in gastric mucosa and intestine, peripheral nerve regeneration and corneal repair (Miguez-Pacheco *et al.*, 2015; Baino *et al.*, 2016; Kargozar *et al.*, 2017b). These novel experimental studies are contributing to further expand the use of glass in medicine and stimulate unconventional research, which could have a great impact on human life and health.

Calcium Phosphate Cements

Aoife Culliton and Eamonn De Barra, University of Limerick, Limerick, Ireland

Introduction

Recent advances in medicine have supported generations of people to live longer. With age comes diminishing quality of bone and hence bone disease and fracture become increasingly more prevalent. In order to aid with fracture fusion and regeneration, bone grafting techniques such as autogenous and allogeneous bone grafts are employed. Their primary functions are to provide structural support to the fracture site and enhance biological fracture repair.

The gold standard in bone grafting are autogenous bone grafts that involve the use of bone harvested from the patient's own body which is seeded with living cells and growth factors. The limitations associated with this technique are significant and include the fact that autogenous bone grafting requires a second surgical site which may result in donor site morbidity, increased post-operative pain and limited supply of bone.

The alternative, allogeneous bone grafting is when bone is harvested from a cadaver. Although this to some degree overcomes the limited supply, there is a significant increase in the transmission of disease and infection from the donor bone and also a risk of rejection. Donor bone has to undergo sterilization to limit these factors however it has an adverse effect on bone strength and biological factors (Zhang *et al.*, 2013).

The limitations associated with the above techniques hence underline the need for a suitable alternative which is free from limitation and disease. The scope of this chapter explores the use of calcium phosphate cements (CPCs) as a suitable alternative which may be used as a bone grafting substitute.

Calcium phosphate cements and their application as a bone cement have been of continuing interest since their introduction to dentistry in 1983 by Brown and Chow (1983) of the American Dental Association. Brown and Chow studied the use of CPCs as a remineralizing paste for the repair of dental carious lesions. By investigating the setting reactions of tetracalcium phosphate (TTCP), dicalcium phosphate anhydrous (DCPA) and dicalcium phosphate dihydrate (DCPD), Brown and Chow inadvertently uncovered a new self-setting orthopedic bone cement consisting solely of calcium phosphates which precipitate a hydroxyapatite (HA) by-product. This was deemed a momentous discovery as hydroxyapatite is the major mineral component of bone and hence the cement will be highly compatible with both soft and hard tissue (Chow and Takagi, 2001).

The CPC setting reaction is a dissolution-precipitation reaction whereby the combination of a powder and liquid phase results in the formation of a cement paste which sets in situ as a solid mass. The initial reaction sees the dissolution of calcium and phosphate ions which work to supersaturate the solution with respect to calcium and phosphate ions leading to the precipitation of the thermodynamically favored calcium orthophosphate phase via a nucleation and crystal growth process. The entanglement of these precipitated needles like crystals of HA is responsible for the hardening of the cement.

According to Hak (2007), the attractiveness of CPCs as an alternative to autogenous bone grafts stems from their bioactive, biocompatible, osteoconductive, and osteointegrative abilities. CPCs promote ingrowth of new living bone and house the ability to display early biological properties similar to that of HA. Studies have confirmed that CPCs once set are incorporated into the bone remodeling cycle and hence undergo osteoclastic resorption, followed by angiogenesis and new bone formation (Bohner, 2000).

In recent years as summarized by Chow *et al.* (1991), there has been a resurgence of interest in optimizing calcium phosphate cements with relation to the setting reaction in order to comply with clinical requirements. At present, calcium phosphate cements are restricted to non-/low-load bearing applications due to their weak mechanical properties. Examples include stabilization of craniofacial surgical sites, and maxillofacial void defect filling. CPCs' weak mechanical properties can be attributed to the highly porous nature of the cement. It has been discussed by Ambard and Muenninghoff (2006) that reduction of the cement's porosity would adversely compromise the cements osteoconductive properties and its ability to be incorporated into the bone remodeling cycle. Other parameters of interest as discussed by Ginebra *et al.* (2004), Fernández *et al.* (1998) and various other published authors include injectability and molding capabilities, powder/liquid ratio, and pH and solubility.

Bone graft substitutes are designed to be osteoconductive i.e., promote either on growth and/or ingrowth of newly formed bone and are traditionally used in conjunction with either/or a potent biologic stimulus or internal and external fixation methods. Currently on the market there are copious amounts of different bone graft substitutes which vary considerably in terms of structural strength, chemical composition and both resorption and remodeling rates. It is therefore paramount for surgical staff to fully understand the differences in order to optimize their use in specific clinical situations (Hak, 2007).

Bone graft substitutes are indicated for filling bone voids and defects where mechanical stability is not its primary function. As stated above, because of their limited structural stability, they are used in conjunction with traditional fixation methods (Hak, 2007).

The ideal biomaterial would exhibit good mechanical stability, be biocompatible and easily shaped and molded for esthetic purposes. According to Henslee *et al.* (2012), calcium phosphate cements display all these qualities.

Table 1 Crystallographic data for known calcium phosphates

<i>CaP</i>	<i>Space group</i>	<i>Unit cell parameters (a, b, c in Å, α, β, γ in °)</i>	<i>Z</i>	<i>Density (g/cm³)</i>
MCPM	Triclinic $\bar{P}\bar{1}$	$a = 5.6261(5), b = 11.889(2), c = 6.4731(8)$ $\alpha = 98.633(6), \beta = 118.262(6), \gamma = 83.344(6)$	2	2.23
MCPA	Triclinic $\bar{P}\bar{1}$	$a = 7.5577(5), b = 8.2531(6), c = 5.5504(3)$ $\alpha = 109.87(1), \beta = 93.68(1), \gamma = 109.15(1)$	2	2.58
DCPD	Monoclinic Ia	$a = 5.812(2), b = 15.180(3), c = 6.239(2)$ $\beta = 116.42(3)$	4	2.32
DCPA	Triclinic $\bar{P}\bar{1}$	$a = 6.190(1), b = 6.627(2), c = 6.9982(2)$ $\alpha = 96.34(2), \beta = 103.82(2), \gamma = 88.33(2)$	4	2.89
OCP	Triclinic $\bar{P}\bar{1}$	$a = 19.693(4), b = 9.523(2), c = 6.835(2)$ $\alpha = 90.15(2), \beta = 92.54(2), \gamma = 108.65(1)$	1	2.61
α – TCP	Monoclinic $P2_1/a$	$a = 12.887(2), b = 27.280(4), c = 15.219(2)$ $\beta = 126.20(1)$	24	2.86
β – TCP	Rhombohedral $R\bar{3}cH$	$a = b = 10.439(1), c = 37.375(6)$ $\gamma = 120$	21	3.07
HA	Monoclinic $P2_1/a$ or hexagonal $P6_3/m$	$a = 9.84214(8), b = 2a, c = 6.8814(7)$ $\gamma = 120$ (monoclinic)	4	3.16
		$a = b = 9.4302(5), c = 6.8911(2)$ $\gamma = 120$ (hexagonal)	2	
TTCP	Monoclinic $P2_1$	$a = 7.023(1), b = 11.986(4), c = 9.473(2)$ $\beta = 90.90(1)$	4	3.05

Calcium Phosphate Salts

Calcium Orthophosphates (CaPs) can be considered as salts of either primary ($H_2PO_4^-$), secondary (HPO_4^{2-}) or tertiary (PO_4^{3-}) phosphate ions and the counter ion Calcium (Ca^{2+}). They are further distinguished by their Calcium to Phosphate ratio, 0.5–2.0 and their crystal structure influencing their physiochemical characteristics and applicability to use as a bone substitute. CaPs can be generally divided between high temperature formation and low temperature precipitate materials. High temperature materials (FA, OA, TTCP, α and β -TCP) are typically formed at temperatures above 1000°C. The solution precipitated materials of Calcium Deficient Hydroxyapatite (CDHA), Dicalcium Phosphate Anhydrous and Dihydrate (DCPA, DCPD), Monocalcium Phosphate Anhydrous and Monohydrate (MCPA, MCPM), Octocalcium Phosphate (OCP) and Hydroxyapatite (HA) are obtained at low temperatures. Typically the phase formed is dependent on the solution pH, supersaturation as well as reaction rate, and typically it is these low temperature precipitate formed calcium phosphate salts that are utilized in the setting reaction of a calcium phosphate cement.

Dorozhkin (2007) states that the primary parameters of interest for calcium phosphate salts are molar Ca/P ratio, solubility and basicity/acidity as these parameters correlate significantly with solution pH. A lower Ca/P molar ratio indicates a more acidic and water-soluble calcium phosphate salt. It has been noted by Bohner (2000) that subtle alterations in the structure and composition of calcium phosphate compounds has a significant effect on their in vivo behavior. The in vivo degradation of a calcium phosphate is largely dependent on their solubility. If the solubility of the calcium phosphate salt is less than that of the mineral component of bone, an extremely slow degradation rate will be observed whereas the opposite is noted if the solubility is greater than that of the mineral component of bone. The following are the most commonly used calcium phosphate salts and their properties (Table 1).

Monocalcium phosphate monohydrate (MCPM) is the most acidic and water-soluble calcium phosphate compound. At temperatures above 100°C, it transforms into MCPA. Due to its high acidity and solubility, MCPM is never found in biological calcifications. However, MCPM is used in some calcium phosphate biomedical applications.

Monocalcium phosphate anhydrous (MCPA) is the anhydrous form of MCPM. It crystallizes under similar conditions as MCPM but at temperatures above 100°C. Like MCPM, MCPA never appears in calcified tissue. Currently it is not used for any biomedical applications.

Dicalcium phosphate dihydrate (DCPD) can be easily crystallized from aqueous solutions. DCPD transforms into dicalcium phosphate anhydrite at temperatures above 80°C. It is metastable and can be converted into the following CaPs: DCPA at pH < 6; OCP at pH 6–7; CDHA at pH > 7 (Bohner, 2000). *In vivo*, DCPD is converted into precipitated HA or biodegraded and replaced by bone. Inflammatory responses may occur when large amounts of DCPD are converted to precipitated HA (PHA) *in vivo*, this is due to the large amount of acid released as shown in the following reaction (Albee, 1920):

DCPD is of biological importance because it is often found in pathological calcifications. It has been detected in fracture callus, bone and kidney stones. It is also sometimes considered a precursor of HA in bone. DCPD is biocompatible, biodegradable and osteoconductive, and thus is used in calcium phosphate cements for biomedical applications.

Dicalcium phosphate anhydrous (DCPA) is the anhydrous form of DCPD. DCPA, like DCPD, can be crystallized from aqueous solutions but at 100°C. Unlike DCPD, DCPA occurs in neither normal nor pathological calcifications. DCPA powder has been tested *in vivo* and has proven to be biocompatible and biodegradable. It is used in calcium phosphate cements.

Octacalcium phosphate (OCP) crystals are triclinic and they consist of alternating apatite layers and hydrated layers. These two layers are linked to each other by Van der Waals and hydrogen bonds. OCP is often found as an intermediate phase during the precipitation of the thermodynamically more stable calcium phosphates like HA, from aqueous solutions. OCP plays an important role in the *in vivo* formation of apatitic biominerals. OCP is also biocompatible, biodegradable and osteoconductive.

Tricalcium phosphate (TCP) exists in two major distinct phases: α -TCP and β -TCP phases. α -TCP crystallizes in the monoclinic space group, and β -TCP crystallizes in the rhombohedral space group. Despite their similar chemical composition, their different crystallographic features give different resorption features: α -TCP is more soluble than β -TCP, and it is obtained after heating the β -TCP to more than 1170°C.

β -TCP is the “true calcium orthophosphate” of the stoichiometric composition $\text{Ca}_3(\text{PO}_4)_2$. It can be obtained through the thermal treatment above 650°C of an equimolar amount of DCPD and PHA (Precipitated hydroxyapatite) at Ca:P ratio of 1.67 and subsequent calcination (Eliaz, 2012). β -TCP cannot be precipitated from solution, but may only be prepared by calcination. At temperatures above 1170°C it transforms into the high temperature phase α -TCP (Dorozhkin, 2009b). Being the stable phase at room temperature, β -TCP is less soluble in water than α -TCP. Pure β -TCP never occurs in biological calcifications. β -TCP is degradable and can be used in combination with HA as a biphasic calcium phosphate (BCP) as a bone substitute.

α -TCP has exactly the same chemical composition as β -TCP but has a different crystallographic structure. α -TCP is more reactive in aqueous systems than β -TCP and can be hydrolyzed to a mixture of other calcium phosphates. It never occurs in biological calcifications and has a limited application in medicine in calcium phosphate cements.

Amorphous calcium phosphate (ACP) is often encountered as a transient phase during the formation of calcium phosphates in aqueous systems. Usually ACP is the first phase that is precipitated from a supersaturated solution prepared by rapid mixing of solutions containing calcium and phosphate ions. The chemical composition of ACP depends on the pH of the solution and the concentrations of the calcium and phosphate ions. Biologically, ACP is found in soft-tissue pathological calcifications. ACP is sometimes used in calcium phosphate cements.

Calcium deficient hydroxyapatite (CDHA) can be easily prepared by the simultaneous addition of calcium and phosphate containing solutions into boiling water, followed by boiling the suspension for several hours. During this time, the initially precipitated OCP or ACP (depending on pH) is transformed into CDHA (Dorozhkin, 2009b). Unsubstituted CDHA does not exist in biological calcifications; it occurs only with ionic substitutions, i.e., sodium for calcium, carbonate for phosphate. This substituted CDHA forms dahllite “the biological apatite” which is the main inorganic component of animal and human normal and pathological calcifications. Therefore, CDHA is a very promising compound for the manufacture of artificial bone substitutes.

Hydroxyapatite (HA) is highly crystalline and is the most stable and least soluble of all calcium orthophosphates. Pure HA crystallizes in the monoclinic space group $P2_1/b$ (Elliott *et al.*, 1973). However, at temperatures above 250°C, there is a monoclinic to hexagonal phase transition in HA (Elliott, 1994). Some impurities, like partial substitution of hydroxide by fluoride or chloride ions, stabilize the hexagonal structure of HA at ambient temperature. For this reason, the very rare single crystals of natural HA always exhibit a hexagonal space group (Elliott, 1994). Pure HA never occurs in biological systems, however, because of the chemical similarities to bone mineral, HA is widely used as a coating for orthopedic and dental implants.

Precipitated hydroxyapatite (PHA) chemistry is very complex. PHA can have a Ca:P ratio from 1.50 to 1.67 (Brown and Martin, 1999). PHA with a Ca:P molar ratio of 1.50 is often called calcium-deficient (CDHA) or tricalcium phosphate (TCP). TCP has almost the same chemical composition as β -TCP but has a different crystalline structure. PHA is obtained by precipitation in an aqueous solution above pH 7 (Bohner, 2000). PHA crystals are poorly crystalline and of submicron dimensions however PHA has a very large specific surface area. Therefore, PHA is very similar to the apatite present in bone. According to literature the solubility of PHA varies by up to 20% depending on the method of preparation (Bohner, 2000). The solubility of PHA increases with a decrease in Ca:P ratio, a decrease in crystallinity and a decrease in crystal size. Depending on Ca:P ratio, on heating above 700°C, PHA degrades into the following (Bohner, 2000):

Table 2 IR and Raman peak positions of hydroxyapatite

- (3) Ca:P = 1.67 PHA → HA

Tetracalcium phosphate (TTCP) is the most basic calcium orthophosphate. However, its solubility in water is higher than that of HA. TTCP cannot be precipitated from aqueous solutions, and thus can only be prepared by a solid-state reaction above 1300°C, for example, by heating homogenized, equimolar quantities of DCPA and CaCO₃. This reaction should be carried out in a dry atmosphere to prevent uptake of water and formation of HA (Dorozhkin, 2009b):

TTCP is not very stable in aqueous solutions, it slowly hydrolyzes to HA and calcium hydroxide. Consequently, TTCP is never found in biological calcifications. TTCP is the most soluble calcium phosphate below a pH of 5. It is also the most basic calcium phosphate. In medicine, TTCP is widely used for the preparation of various self-setting calcium phosphate cements. It is bio-compatible but despite its high solubility it is poorly biodegradable.

Hydroxyapatite

Up to 70% of bone is made up of an inorganic mineral called hydroxyapatite, which includes calcium phosphate, calcium carbonate, calcium fluoride, calcium hydroxide and citrate (Ooi *et al.*, 2007). Hydroxyapatite is predominantly crystalline. The properties of hydroxyapatite, both natural and synthetic, vary widely. Hydroxyapatite being the crystalline component of bone, is the most commonly used calcium phosphate in implant/bone filler fabrication. Synthetic HA has such chemical similarity to bone

Fig. 1 ^{31}P MAS NMR of Hydroxyapatite showing resonance at 2.8 ppm relative to 85% H_2PO_4 . Reproduced from Chappell, H., Duer, M., Groom, N., Pickard, C., Bristowe, P., 2008. Probing the surface structure of hydroxyapatite using NMR spectroscopy and first principles calculations, *Physical Chemistry Chemical Physics*. 10 600–606.

mineral that it will induce a biological response similar to the one generated during bone remodeling. Hydroxyapatite is one of the few materials that are classified as bioactive, meaning it will support bone ingrowth and osseointegration when used in orthopedic, dental and maxillofacial applications. The key properties of synthetic HA are (1) its ability to integrate in bone structures and support bone ingrowth, without breaking down or dissolving, (2) HA is a thermally unstable compound, decomposing at temperatures from about 800–1200°C depending on its stoichiometry, (3) generally speaking dense hydroxyapatite does not have the mechanical strength to enable it to succeed in long term load bearing applications (Dorozhkin, 2009b).

Hydroxyapatite has a similar structure to octacalcium phosphate (OCP) ($\text{Ca}_8(\text{HPO}_4)_2(\text{PO}_4)_4$) and there is a strong relationship between these two compounds.

The nucleation of hydroxyapatite depends upon reaction conditions. In highly supersaturated solutions at neutral or alkali pH conditions, it was shown that amorphous calcium phosphate first forms which then transforms to OCP which then hydrolyzes to Hydroxyapatite (Elliott, 1994). In studies where seeded crystals were added to calcium phosphate solutions with altering conditions showed that the rate of crystal growth is largely determined by the degree of the supersaturation of the surrounding solution (Moreno *et al.*, 1977; Moreno and Varughese, 1981). Kinetic analysis showed that linear growth rate was dependent on the square of the degree of supersaturation of the solution (Moreno *et al.*, 1977; Moreno and Varughese, 1981).

Infrared and Raman spectroscopy techniques can be used for identification of phases within a sample (Table 2).

NMR Spectroscopy of HA

In ^1H MAS NMR of hydroxyapatite at 500.13 MHz and a spinning speed of 7.3 kHz a sharp resonance was present at 0.2 ppm relative to trimethyl silane which was attributed to the proton in the OH^- group, a second resonance at 5.6 ppm was identified which was attributed to surface adsorbed water (Yesinowski and Eckert, 1987). ^{43}Ca MAS NMR has been performed on hydroxyapatite samples in an attempt to distinguish between the two Ca sites with Ca(I) located at -1.8 ± 0.8 ppm and Ca(II) at 11.2 ± 0.8 ppm (Laurencin *et al.*, 2008). ^{31}P MAS NMR studies were also carried out on hydroxyapatite at 68 MHz and a spinning speed of 2.5 kHz and gave a resonance at 2.8 ppm relative to 85% H_3PO_4 . The authors also produced a number of calcium-deficient apatites with Ca/P – 1.46 & 1.58. These also gave resonances at 2.8 ppm indicating no difference in peak position with changing stoichiometry (Rothwell *et al.*, 1980) (Fig. 1).

X-ray Diffraction of HA

The XRD pattern below is that of Hydroxyapatite. The characteristic peaks are the triplet peaks around 32 degrees 2 theta (31.7 (211)), 32.1 (112 and 32.8 (300)° 2θ). There is also a characteristic line at 25.8 (002)° 2θ (Fig. 2).

Octacalcium Phosphate

Octacalcium phosphate (OCP) has the chemical formula $\text{Ca}_8(\text{HPO}_4)_2(\text{PO}_4)_4 \cdot 5\text{H}_2\text{O}$. Octacalcium phosphate, which is structurally similar to hydroxyapatite, is a possible precursor in the formation of apatitic calcium phosphate minerals in bones and teeth (Brown and Chow, 1990). OCP is more soluble and less stable at physiological conditions than hydroxyapatite. The similarity of

Fig. 2 X-ray Diffraction pattern and relative intensities of Hydroxyapatite. JCPDC ref code 009-0432.

the apatite layer in OCP and the apatite structure in HA provides geometrically favorable conditions for phase transformation from OCP to HA. OCP tends to convert to HA not only in an in vitro environment, but also as an implant in bone defects. This intermediary, however, is thought to be pH dependent. OCP will be an intermediate phase before hydroxyapatite formation at pH between 5.0 and 9.0 whereas if reaction conditions are above pH 9.0 then hydroxyapatite will precipitate directly (Chow, 2000). It has been proposed that the transformation of OCP to HA follows a dissolution-precipitation process (Elliott, 1994). Solid state transformation of OCP to HA has also been suggested in the work of (Nakamura *et al.*, 2006) where the transformation was induced by electron beam irradiation in TEM and the crystal structure change was observed using bright field images, electron diffraction and high resolution microscopy. Studies have shown that resorption of OCP is followed by replacement of newly formed bone (Markovic and Chow, 2010).

Crystals of OCP are typically small and plate-like. The crystals are triclinic, space group P1, with cell parameters $a = 19.692 \text{ \AA}$, $b = 9.523 \text{ \AA}$, $c = 6.835 \text{ \AA}$, $\alpha = 90.15^\circ$, $\beta = 92.54^\circ$, $\gamma = 108.65^\circ$ and $z = 2$. The crystal structure of OCP is described as an alternative stacking of apatite layers and hydrated layers along its [100] direction (Chow and Takagi, 2001). The apatite layer is approximately 1.1 nm thick and is alternating with the water layers which are approximately 0.8 nm thick, parallel to (100) and are a clear feature of the OCP structure (Elliott, 1994) (Fig. 3).

The apatite like layer provides an explanation for the similarities seen in the lattice parameters of OCP and HA ($a = 9.4176$, and $c = 6.8814 \text{ \AA}$). This apatite layer is made of alternating sheets of phosphate ions with Ca^{2+} ions. The water layer consists of phosphate ions more widely spaced than the apatite later and Ca^{2+} ions with a slightly variable amount of water molecules between them. The constituent ions in the OCP structure are distributed between these two layers differently. Six Ca^{2+} ions and two of the six phosphates are located in the apatite layer. The water layer is made of two Ca^{2+} ions and a single phosphate ion. This leaves three phosphate ions which are located in the junction between the apatite and water layers. Two of the phosphate ions are protonated, the phosphate ion in the water layer and one of the phosphate ions located at the inter layer junction (Elliott, 1994).

NMR Spectroscopy of OCP

^1H MAS NMR performed at 500 MHz and a spinning speed of 7.8 kHz showed the presence of a chemical shift at 13 ppm referenced to trimethyl silane and this was assigned to an acidic proton of a HPO_4^{2-} ion located in the junction between the apatite and water layers. The other HPO_4^{2-} located in the water layer was not found. The failure to find a clearly resolved resonance was attributed to positional disorder of this ion and overlap with resonances with the structural water found in OCP. Chemical shifts at 1.1 and 1.5 ppm were detected and were assigned to protons on an isolated water molecule found in the OCP water layer. At 5.5 ppm there was an intense spinning sideband pattern that was assigned to relatively immobile structural water groups. The intensity of this resonance was attributed to a more mobile water species either in the OCP water later or on the OCP surface. ^1H MAS NMR studies performed on thermally dehydrated OCP (a process known to induce OCP to HA transformation) gave a resonance at 0.2 ppm which was attributed to the OH^- found in HA. This was attributed to as evidence of the theory that the structural water in OCP can relocate themselves to a nearby PO_4^{3-} to form HPO_4^{2-} and OH^- in a dehydration reaction of OCP to form HA (Elliott, 1994).

A ^{31}P MAS NMR study performed on OCP (121 MHz, spinning speed 6 kHz) prepared through a reaction of sodium phosphate monobasic dihydrate ($\text{H}_2\text{NaPO}_4 \cdot 2\text{H}_2\text{O}$) and calcium nitrite tetrahydrate $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$. The OCP sample gave four resonances relative to 85% H_3PO_4 and -0.2 , 2.0 , 3.3 and 3.7 ppm. The resonance at 0.2 ppm was assigned to P5 and P6; the resonance at 2.0 ppm was P3; 3.3 ppm was P2 and P4; lastly 3.7 ppm was attributed to P1. Phosphates labeled P1–4 are the PO_4^{3-} ions in the OCP structure and P5 & P6 are the HPO_4^{2-} ions (Tsai *et al.*, 2010; Tseng *et al.*, 2004; Davies *et al.*, 2012) (Fig. 4).

Fig. 3 Crystal structure of octacalcium phosphate. Reproduced from Cazalbou, S., Combes, C., Eichert, D., Rey, C., 2004. Adaptive physico-chemistry of bio-related calcium phosphates. *Journal of Materials Chemistry* 14, 2148–2153.

Fig. 4 ^{31}P MAS NMR of Octacalcium Phosphate showing resonances at -0.2 , 2.0 , 3.3 and 3.7 ppm relative to $85\% \text{H}_2\text{PO}_4$. Adapted from Drouet, C., 2013. Apatite formation: Why it may not work as planned, and how to conclusively identify apatite compounds *BioMed Research International* 2013, 490946.

X-Ray Diffraction

Fig. 5 shows the reference XRD pattern of OCP. Given the similarities between the pattern for OCP and HA, the only diffraction line where OCP can be distinguished from HA is the diffraction line at $4.7^\circ 2\theta$, which in highly crystalline OCP will give an intense diffraction line.

Dicalcium Phosphate Dihydrate

Brushite or dicalcium phosphate dihydrate (DCPD) ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$) was discovered in 1865 in phosphatic guano in the Caribbean. It is proposed that Brushite is an intermediate for apatite formation, indeed if Brushite is placed into a pH solution outside of its solubility range then apatite will form (Elliott, 1994).

Fig. 5 X-ray Diffraction pattern and relative intensities of Octacalcium Phosphate. JCPDC ref code 026-1056.

Structure

DCPD is monoclinic, space group *1a* with lattice parameters $a = 5.812 \pm 0.002$, $b = 15.180 \pm 0.003$, $c = 6.239 \pm 0.002$ Å and $\beta = 116^\circ 25' \pm 2'$. Four formula units are present per unit cell with an asymmetric unit $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$, none of the 5 hydrogen atoms are related by symmetry (Curry and Jones, 1971). The structure of DCPD consists of columns that are parallel to the short diagonal of the (010) face of the unit cell, of alternating Ca^{2+} and PO_4^{3-} ions. The columns are joined together to form corrugated sheets, a conspicuous feature of the structure. The sheets have the composition CaHPO_4 and are linked together by water molecules. Similarly structured sheets are also notable found in the structure of $\text{Ca}(\text{H}_2\text{PO}_4)_2 \cdot \text{H}_2\text{O}$ (Elliott, 1994).

Hydrolysis of DCPD will ultimately lead to formation of HA. However, unlike the relationship between OCP and HA, DCPD is not a pseudomorph of HA (Elliott, 1994). Where the transformation of OCP to HA goes via a solid state phase transition, the single crystal unit is altered chemically to give the formula of HA. In DCPD to HA transformation the route of formation is through dissolution of DCPD then precipitation of HA which can go via OCP as an intermediate depending upon reaction conditions.

DCPD will transform to OCP if in a solution with a pH range 6.2–7.4 and at a temperature within 25–37°C (Tung *et al.*, 1985). If reaction conditions have a higher pH or temperature than this then it is believed that HA will precipitate directly. The reason for this is that the precipitation and growth rate of HA is slow if the pH or temperature is not high; this is in contrast to OCP which has a lower solubility than DCPD and will form readily in mild conditions.

Below are the IR and Raman frequencies for DCPD. DCPD can be distinguished from its bands at 875 cm^{-1} (IR) and 880 cm^{-1} (Raman), which are P-O(H) stretching (Table 3).

NMR Spectroscopy of Dicalcium Phosphate Dihydrate

^{31}P MAS NMR (2 kHz, spinning speed) ^1H decoupled at 68 MHz studies performed on DCPD samples have shown a resonance at 1.7 ppm relative to 85% H_2PO_4 . ^1H MAS NMR studies have shown resonances at 6.4 and 10.4 ppm referenced to trimethyl silane which were attributed to structural water and acidic protons respectively. This was performed at both 200 and 500 MHz with a spinning speed up to 8 kHz (Miquel *et al.*, 1990) (Fig. 6).

X-Ray Diffraction Dicalcium Phosphate Dihydrate

DCPD can be distinguished from OCP and HA by its peak at $11.607^\circ 2\theta$ as shown in Fig. 7.

In Vivo use of Calcium Phosphates

All calcium phosphates are osteoconductive which means bone bonds directly to the surface without an intervening soft tissue layer (Williams, 1987). Osteoconduction helps to increase the activity of bone forming cells – osteoclasts. This osteoconductive property of calcium phosphates, combined with suitable porosity, provides a powerful bone growth scaffold.

The first in vivo use of calcium phosphates has been shown to date back to the 1920s, when tricalcium phosphate (TCP) was implanted to test its efficacy as a bone substitute. The data compared bone fractures with bone loss, and showed that bone growth and union, when injected with calcium phosphate, healed faster than did the controls without its use (Dorozhkin, 2009a; Chow, 2009). Over the next few decades various calcium phosphate particles were implanted into animal specimens to test their effect on

healing with hydroxyapatite (HA) being implanted into rats and guinea pigs for testing in 1951 (Bohner *et al.*, 2000b; Dorozhkin, 2009a). Despite these early experiments however, it was not until the early 1970s that the stigma and fear of utilizing non inert materials within the physiological environment was challenged by researchers who investigated the implantation of soda lime-phosphate silicate glass compositions in the femurs of rats (Hench, 1991; Pattanayak *et al.*, 2011). These implanted bioactive materials were investigated, synthesized and characterized. The results indicated that the materials bonded to the living bone without forming interfacial scar tissue. Extensive toxicity studies on these materials have demonstrated a high degree of biocompatibility, minimal if any inflammatory response or foreign body response and no evidence of local or systemic toxicity. This is because calcium and phosphate ions are the most common ions in the body and these compounds allow direct bonding of soft tissue or bone cells. Since then, focus on these bioactive materials has increased significantly, with the idea of developing calcium phosphate based cements being investigated Brown and Chow (1983).

Calcium Phosphate Cements (CPCs)

The development of the first self-setting calcium phosphate cement was reported in 1987 by Chow (Chow and Takagi, 2001), (Sanzana *et al.*, 2008), (Chow, 2009). These pastes were based on the solubility properties of calcium phosphates being greater than HA in the physiological environment.

One of the great challenges facing modern medicine is to replace old, deteriorating bone with a material that can function for the remaining years of the patient's life and, ideally, be replaced by new bone. This is the theory behind the development of calcium phosphate cements, which are resorbable biomaterials and are designed to gradually degrade over a determined period of time and be replaced by naturally forming host tissue, resulting in a very thin or non-existing interfacial bond. The aim of CPC's is

Fig. 6 ^{31}P MAS NMR of dicalcium phosphate dihydrate showing resonance at 1.7 ppm relative to 85% H_2PO_4 . Adapted from Drouet, C., 2013. Apatite formation: Why it may not work as planned, and how to conclusively identify apatite compounds. *BioMed Research International* 2013, 490946.

Fig. 7 X-ray Diffraction pattern and relative intensities of dicalcium phosphate dihydrate. JCPDC ref code 009-0077.

to disturb bone functions and properties as little as possible and to behave temporarily in a manner similar to that of bone. These CPC's must form and reproduce the structure, crystallinity, morphology and composition of bone crystals (Hench, 1991; Dorozhkin, 2009a, 2010).

Calcium phosphate cements are synthetic bone graft materials that consist essentially of only calcium phosphate compounds and are capable of self-setting to a hard mass. Synthetic, self-setting, CPC's generally consist of a powder and an aqueous liquid, which are mixed, resulting in a paste-like consistency. They can be molded and even injected via syringe before they harden in situ with fast setting times. This hardening occurs without excessive heat production and at favorable pH levels. Also CPC's allow the surgeon to shape and implant the bioactive bone substitute material on a patient-specific base in real time. This versatility is a key distinguishing characteristic of CPC's from prefabricated calcium orthophosphate granules or blocks. Upon mixing, the powder dissolves in the aqueous solution and new forms of crystals precipitate, the reaction proceeds until all reactive calcium phosphate compounds react. Cement hardening occurs with the entanglement of calcium phosphate crystals, hence leading to a highly porous structure. CPC's exhibit bioactive behavior and integrate into the bone structure by a physiochemical bond as part of bone remodeling process.

The advantages of CPCs include being injectable, moldable and the ability to adapt to the bone defects. They also exhibit excellent biocompatibility and osteoconductive properties. However, because of their limited compressive strength, they are limited to non-load bearing applications such as maxillofacial surgery, the repair of cranial defects and dental fillings. In 1996 the FDA cleared the first calcium phosphate cement for clinical use for non-load bearing applications called BoneSource™ Hydroxyapatite Cement (Friedman *et al.*, 1998; Xu *et al.*, 2007). This self-setting bioactive CPC forms biocompatible precipitated HA as the end product and is, in small defects, gradually replaced by new bone over time, without a loss in volume.

Table 4 Commercial compositions of calcium phosphate cements

Company	Cement/ name	Components	End product
ETEX	a-BSM Embarc Biobon	Powder: ACP (50%), DCPD (50%); Solution: H ₂ O (unbuffered saline solution)	Apatite

Biodegradation/Bioresorption of Calcium Phosphate Cements and Replacement by New Bone

Biodegradation is the process caused by the action of living systems whereby a material is broken down into its simpler components. Resorption of bone in vitro or in vivo has been described as cell-mediated degradation of the inorganic and organic phases of bone (Barrère *et al.*, 2006). The process of biodegradation/bioresorption of CaP materials results in physicochemical changes after contact with the biological environment. The physical changes may include disintegration, loss of mechanical strength, loss of density, and change in porosity. The chemical changes include reduction in the pH of the implant environment causing partial dissolution of the material. Chemical changes may also include elevation in the concentrations of calcium and phosphate ions in the environment leading to the formation of other CaP phases. CPCs are bioactive which means they can form a chemical bond with the bone tissue, resulting in a strong bone/material interface. Biodegradation/bioresorption of the material is believed to be related to the solubility of the CaP materials. CaP materials of different composition differ in their crystallographic structure and therefore in their internal bonding strength which is reflected in their stability and solubility or dissolution properties. Even CaP materials of identical composition but different crystallographic structure i.e., α -TCP and β -TCP, vary in their dissolution properties in vitro and also vary in their extent of biodegradation. The differences in biodegradation/biodissolution of CaP materials of similar composition but of different crystallinity may be associated with crystal sizes and the amount of lattice defects present. Smaller crystals will dissolve more readily than larger crystals of the same composition due to the larger surface area exposed to the biological environment.

In theory, calcium phosphate cement may be substituted by bone depending on its formulation and particle size. Apatite CPC was implanted as a paste into the femoral bone of dogs for 3 and 6 months. Histology was performed on thin un-decalcified sections. No foreign body reaction, no inflammation and no necrosis were found. It was found that new bone was formed directly on the resorption line of the calcium phosphate cement whereby a creeping substitution of cement by bone had taken place (Yuan *et al.*, 2000). Osteoclast like cells resorbed the cement as if the cement was bone and replaced the cement with new bone. This is an important property, as the cement could provide short-term biologically desirable properties and then be replaced by new bone. Bone substitution depends on porosity, crystallinity, chemical composition, particle size and powder/liquid (P/L) ratio of the cement.

Solubility of Calcium Phosphates in Calcium Phosphate Cements

Extensive research on new CPC compositions has shown that cementation can occur in mixtures containing a wide variety of calcium phosphate compounds (Chow and Eanes, 2001). Table 4 shows a list of calcium phosphates which have been used as cement ingredients, some of which have been shown to be products in other cement systems. The calcium phosphates in Table 4 are listed in order of increasing Ca/P molar ratio. This is also the order of increasing basicity. Solubility is one of the most important properties of calcium phosphate compounds. The solubility of a CaP determines the equilibrium of almost all ambient-temperature chemical reactions in which calcium phosphates are involved. Gravimetric solubility, defined as the mass of a solid that can dissolve into a unit volume of solution, is a simple way of describing solubility. However, this quantity can change significantly with pH and other solution parameters so is not suitable to describe the solubility properties of CaPs. A more fundamental parameter for describing solubility is the thermodynamic solubility product constant, K_{sp} . K_{sp} is defined as the equilibrium constant for a solid substance dissolving in an aqueous solution. It represents the level at which a solute dissolves in solution. The more a substance dissolves, the higher the K_{sp} value it has.

The reactions between calcium phosphate compounds that occur in an aqueous environment can be described as dissolution/precipitation reactions. Upon mixing, the calcium phosphates dissolve and precipitate into a less soluble form of CaP. During the precipitation reaction, the CaP crystals grow and become entangled, thus providing mechanical rigidity to the cement. For example, in the TTCP/DCPA cement paste, dissolution of TTCP and DCPA in water leads to a solution composition that is highly supersaturated with respect to calcium and phosphate, resulting in HA precipitation. Such reactions are driven by the solubilities of the reactants and product for a given composition.

Solubility is described as the amount of a solid that can dissolve into a unit volume of solution. For calcium phosphates, this quantity can change by several orders of magnitude with changes in pH and concentrations of acids and bases (Chow, 2009). A solubility phase diagram is shown in Fig. 8. Each curve in the diagram, known as a solubility isotherm, can be calculated from the solubility product constant (K_{sp}) of the compound (Table 4). The isotherm describes the solubility of a salt, expressed as the total calcium and total phosphate concentrations of the saturated solution as a function of pH. The phase diagram is also shown in a two dimensional graph, in which a salt whose isotherm lies below that of another salt is less soluble (more stable). The point where two isotherms cross is known as a singular point. The solution at the singular point is simultaneously saturated with respect to both salts.

The setting reactions may be understood by analysing the solubility of the individual cement components such as TTCP and DCPA. The solubility phase diagram showing the solubility curves of TTCP, DCPA and HA is given in Fig. 9.

Over a range of pH, HA is the least soluble salt with DCPA becoming the least soluble when the pH falls below 4.2. TTCP is the most soluble salt at pH below 9. The relative stability of TTCP and DCPA is a major driving force for the setting reactions with both considerably more soluble than HA at pH above 4.2. As a result, a solution saturated with respect to TTCP (or DCPA) is supersaturated with calcium and phosphate ions leading to HA precipitation (Chow and Takagi, 2001). If the solubility of a calcium phosphate e.g. Hydroxyapatite, is less than the mineral part of bone, it degrades very slowly if at all. However, if the

Fig. 9 Solubility ternary system, $\text{Ca}(\text{OH})_2\text{-H}_3\text{PO}_4\text{-H}_2\text{O}$, at 25°C showing solubility isotherms of TTCP, DCPA and HA. Reproduced from Chow, L.C., Takagi, S., 2001. A natural bone cement – A laboratory novelty led to the development of revolutionary new biomaterials, *Journal of Research of the National Institute of Standards and Technology* 106, 1029–1033.

solubility of a CaP is greater than that of the mineral part of bone it is degraded. Therefore, using the different solubility isotherms of CaP at pH 7.0 the in vivo degradation rate of CaP can be predicted to be in the order of (Chow, 2009):

$$\text{MCPM} > \text{TTCP} \approx \alpha\text{-TCP} > \text{DCPD} > \text{DCP} > \text{OCP} > \beta\text{-TCP} > \text{PHA} > \text{HA}$$

Initially, the setting reaction of CPC starts with dissolution of the calcium phosphate salts in the aqueous system. This dissolution supplies the Ca and P ions, which precipitate in the form of HA with the reaction occurring under isothermic conditions and physiological pH. After initial setting, needle-like crystals enlarge epitaxially and are responsible for the adherence and interlocking of the crystalline grains, which result in hardening. As CPC forms HA in an aqueous environment at body temperature, it results in a relatively low crystallinity HA that is more similar to biological apatites than non-resorbable sintered/ceramic HA formed at high temperatures (Carey *et al.*, 2005).

As mentioned previously, HA is the most stable compound over a wide pH range. For this reason, most neutral pH CPC formulations would form HA or similar apatitic phases such as Ca-deficient HA or carbonated HA. TTCP and DCPA are the most soluble salts and for this reason they were used in the first HA-forming CPC, thus providing the greatest driving force for the HA-forming reaction. As the only calcium phosphate salt with a Ca/P ratio higher than that of HA, TTCP can be combined with lower Ca/P ratio calcium phosphate salts such as DCPA to formulate a mixture that has the stoichiometry of HA. As long as both DCPA and TTCP are present in excess and the dissolution of these two salts is greater than the rate of HA formation, the solution remains near the singular point of pH 8 for these two salts. Thus, during HA formation, the pH of the cement will be only slightly higher than physiological pH which may contribute to high biocompatibility. It should be noted, however, that Figs. 8 and 9 are representative of equilibrium conditions and do not provide information on the kinetics of the dissolution/precipitation process.

The cement setting reaction determines the intermediate and the final products that will be formed in a CPC. Consequently, the type and rate of reaction phases formed and morphologies and thus determines the mechanical and biological properties of the cement. Formation of different calcium phosphate phases as the major cement product offers an effective means for formulating CPCs with a range of in vivo resorption rates. Different formulations will result in various pH conditions depending on the setting reaction. A CPC with a desired pH can be tailored to gain compatibility with components such as osteoinductive factors, antibiotics etc.

There are two classes of CPC's which exist: HA/Apatite forming and DCPD forming cements. Both have excellent biocompatibility and have excellent potential for their common applications.

Apatite and DCPD Forming CPCs

DCPD cements have a higher rate of resorbability, which is believed to be due to DCPD being more soluble than HA (Dorozhkin, 2009b). DCPD cements have been shown to resorb faster than apatite cements and as a result, DCPD cements suffer from a rapid decrease in strength, though overall strength of implanted bone increases due to bone ingrowth (Nishimura *et al.*, 1991).

Apatite cements have better material properties than DCPD cements. DCPD cements have short setting times (~ 30 s) compared to apatite cements (10 min) (Mirtchi *et al.*, 1989). The short setting time of DCPD cements is often considered a

disadvantage as the surgeon will not have sufficient time for the paste to be loaded into the implantation device and implanted before the material sets, making it difficult to use these cements clinically. Attempts to lengthen the setting time include using less soluble reactants, addition of pyrophosphates which have been shown to inhibit setting. One thing which does not appear to have been documented much is the effect of particle size which hypothetically could be used to manipulate setting times.

Apatite cements appear to have wider clinical use than DCPD cements. Currently there are 18 different formulations (Bohner *et al.*, 2005) of apatite cements compared to 3 DCPD cement formulations (Tamimi *et al.*, 2012). This poses the question of why DCPD cements are less popular regardless of their faster resorbability and high initial strength. Dorozhkin (2009b) suggests that the reason for this imbalance is simply that apatite cements were developed before DCPD cements meaning there is a great amount of research done on apatite cements. Therefore, there is large scope for the development of DCPD cements.

Chemistry of Setting in Calcium Phosphate Cements

The most important property of CPC is the cement setting reaction. The nature of the cement products and the physical and biological properties of the hardened cement are determined by the cement setting reaction.

Hydroxyapatite Cement

As previously mentioned, HA cements are the most common and most commercially used group of CPCs. HA cements were the first composition developed by Brown and Chow in 1986 and the setting reaction is shown below.

This simplified reaction highlights the ions which are required for HA formation. Ca^{2+} and PO_4^{3-} ions are usually delivered in the form of various calcium phosphate salts. A pH above 7 is required to provide a source of OH^- ions during the setting reaction.

Brushite (DCPD) Cements

DCPD cements were discovered and developed after the discovery of apatite cements in 1987 by two independent research groups, Mirtchi and Lemaitre (Mirtchi *et al.*, 1989). The first DCPD cements were prepared by mixing MCPM and β -TCP and adding water. The resulting paste was shown to set via an exothermic reaction.

Setting reaction: There are a number of different reactions to form DCPD cements, a selection of these are listed below.

There are 4 steps involved in the setting mechanism for DCPD, (1) the constituents of the cement starting material powder dissolve in water; (2) the dissolved ions form a super-saturated gel; (3) nucleation of DCPD crystals occurs within the gel phase; (4) crystal growth from the nucleated small crystals, these crystals interlock giving a hard set cement (Tamimi *et al.*, 2012). DCPD is soluble above pH 6, therefore DCPD can only precipitate at pH < 6. In cement systems containing β -TCP and MCPM as reactants, studies have shown that over the course of setting, initially the MCPM starts to dissolve which causes a rapid decrease in pH to 2.5 (Bohner *et al.*, 2005, 1997) and then pH increases during the setting reaction to pH 5. The pH in the cement system can be altered (pH 2.5–6) by using different ratios of each of the starting materials; if more MCPM is used the pH will remain low even after setting has completed whereas if excessive β -TCP is used the pH can be almost neutral at pH 6 (Bohner *et al.*, 1997).

Another study by Bohner *et al.* examined a cement reaction where MCPM was replaced with orthophosphoric acid. This system showed good control over reactivity and composition, faster preparation, longer setting times and higher tensile strengths. However, the pH of orthophosphoric acid is lower than that of MCPM resulting in a pH of 2.5 in the cement system both during setting and after the setting reaction is complete. This low pH raises concerns in relation to biocompatibility and potential inflammation (Bohner *et al.*, 1997).

Setting Rate/Reaction Rate

The setting rate of CPCs is a very important handling property because it directly affects the clinical procedure. Too early a setting reaction limits the time the surgeon can spend applying and sculpting the cement, whereas too late a setting reaction results in a longer operating procedure which increases risk to the patient. A number of strategies exist to modify the setting rate of cements, for example, changing the particle size of the reagents, adding a nucleating phase or dissolving accelerators or retarders into the liquid phase (Bohner, 2010). Adding a neutral phosphate such as disodium hydrogen phosphate or sodium dihydrogen phosphate to the liquid phase reduces setting time. In the case of a paste containing dicalcium phosphate and tetracalcium phosphate,

this is possible because the formation of HA and the dissolution of dicalcium phosphate during the setting reaction occur in a linear fashion, thus avoiding early formation of HA. This is important because HA formed early during the setting reaction of the original formulation engulfs unreacted dicalcium phosphate particles (Dorozhkin, 2009a). Therefore, dicalcium phosphate cannot dissolve because it becomes isolated from the solution and thus the setting reaction is slower.

Factors Affecting the Setting Reaction, Paste Stability and Injectability

Although the chemical reactions depend on the chemical composition of the system, setting and hardening of the cement paste is predominantly controlled by the dissolution and precipitation processes in the cement system. A number of additional factors have been reported to influence the resulting CPC setting properties. The modification of parameters such as using additives, varying the Ca/P molar ratio, the powder/liquid ratio in the system, and the particle sizes, specific surface areas and morphology of the cement components, will result in a material that can be tailored to specific clinical requirements and applications. Of particular importance is how such factors can be used to control setting time, for example, a setting reaction that is too fast limits the period during which the surgeon can apply the cement, whereas a setting reaction that is too slow prevents the surgeon from closing the defect and hence extending the overall procedure duration.

The injectability of CPCs is of crucial importance for surgical procedures utilizing minimally invasive procedures or for delivery of the cement into a very narrow space, and is related to the ability of a paste to remain homogeneous under pressure and avoid filter-pressing. Currently, injectable CPC products are delivered as two components consisting of a powder and aqueous liquid, which are mixed in the operating room. After mixing, the paste like cement is injectable and malleable for a few minutes, depending on the type of cement, temperature, etc. and, following injection, the cement hardens in situ.

In addition to a large number of parameters relating to CPC composition (e.g., particle size and shape, particle size distribution, powder/liquid ratio, liquid viscosity, etc.), the injectability of a setting cement depends strongly on the post-mixing time interval relative to the cement setting time. Hence, premixed CPCs that do not harden until being placed into the defect are an advantage.

Use of additives

Through incorporation of setting accelerators such as phosphoric acid into the liquid phase, the setting time of the product can be greatly reduced while additives such as citric acid ensure a desirable initial working time prior to rapid hardening due to impedance of the dissolution-precipitation reactions in the cement. These additives promote dissolution of the solids by lowering the solution pH resulting in an increased rapid cement hardening setting time in the range of 10–15 min (Chow, 2009; Dorozhkin, 2009a).

Used as a hardening accelerator, MCPM has been observed to dissolve quickly in water and, through precipitation, form phosphoric acid and small crystals of DCPD throughout the paste, thus promoting HA formation and paste hardening.

The inclusion of additives such as propylene glycol produces a soft paste that significantly increases the injectability of the CPC. With the addition of citrate ions to the cement paste, there is a chemical interaction between the additive and the calcium phosphate particles. This interaction can modify the particle interactions and hence the physico-chemical properties of the cement, in particular the injectability. The same citrate ions have previously been highlighted as they modify the setting reaction and postpone the full hydrolysis of the calcium phosphate.

Ca/P molar ratio

The Ca/P ratio of the cement system is controlled by the relative amounts of MCPM, DCPA and TTCP present in the two pastes with a decrease in the Ca/P ratio resulting in an increased setting reaction rate. Ishikawa (2014) suggested the formation of nearly stoichiometric HA (Ca/P ratio of 1.66) when excess TTCP was present and formation of Ca-deficient HA when excess DCPA was present in the TTCP + DCPA cement. As described in Chow *et al.* (2005), HA formed in neutral or mildly acidic pH conditions is expected to have a Ca/P ratio of approximately 1.5. Accordingly an overall Ca/P ratio of 1.5 in the formulation should lead to the situation that HA is the only cement product. A Ca/P ratio of > 1.33 is believed to yield HA as the major phase in the product. Although stoichiometrically the Ca/P molar ratio in TTCP is 2, a Ca/P molar ratio of 1.9 is usually targeted for TTCP manufacture to avoid the formation of calcium oxide (Chow *et al.*, 2005).

By decreasing the TTCP/DCPA ratio from Brown and Chow's (1983) traditional ratio of 1 to 0.33 (yielding overall Ca/P ratios of 1 and 1.33), Xu *et al.* (2007) increased the CPC dissolution rate by 40% compared with the CPC control ratio of 1 without compromising the setting time or the strength and modulus which exceeded those of natural cancellous bone. In contrast, a significant decrease in strength and modulus was observed in the increased ratios of 2 and 3. Xu *et al.* (2007) selected the TTCP/DCPA ratios of 2 and 3, as a ratio of 1 results in stoichiometric HA and a ratio of 0.5 results in Ca-deficient HA, which has a faster dissolution rate than stoichiometric HA (Matsuya *et al.*, 2000). Similar results were also reported by Hirayama *et al.* (2008).

Powder/liquid ratio

The powder/liquid ratio is hugely influential on both the paste handling characteristics and the setting reaction as it determines the water content in the cement available for reaction. The liquid phase can be water, saline, or other physiological like fluid. A phosphate containing solution can be used for a shortened working time with a non-aqueous but water-miscible liquid such as

glycerol or polyethylene glycol for applications that require a longer working time. Water plays an important role in cements as initially, it is involved as a dissolution medium for the calcium phosphates and secondly, it is involved in the formation of DCPD or OCP. Nevertheless, it is important to note that the quantity of water actually needed by the overall formation of the cement is relatively small (Lacout *et al.*, 1996).

The P/L ratio affects the injectability of the paste. A study by Khairoun *et al.* (1998) observed that the paste injectability increases with an increasing L/P ratio from 0.35 to 0.40, thus decreasing viscosity of the paste (i.e., varies inversely with its viscosity). When a paste, which is a two component mixture of a finely divided ceramic powder and a liquid is submitted to a pressure gradient, the liquid may flow faster than the solid, resulting in local changes in the solid dispersion. This previously mentioned phenomenon of filter-pressing may have a knock on effect on the paste injectability. In addition, the powder/liquid ratio also affects the mass amount of calcium phosphate components in a given volume of the paste. This in turn, contributes to the paste viscosity and the porosity and strength of the hardened cement mass. It also affects the overall Ca/P ratio of the formulation.

pH and temperature

An important in vivo characteristic of HA-forming CPC is that it does not dissolve spontaneously in a normal physiological fluid environment, yet it is resorbable under cell-mediated acidic conditions. The pH, presence of water, time and temperature all have a strong effect on the decomposition of DCPD to DCPA with a study by Bohner *et al.* (2000a,b) confirming low pH and high temperature trigger this decomposition. An increase in acidity has also been shown to accelerate the cement setting reaction and therefore to decrease the setting time (Bohner *et al.*, 2000a). The solubility of the injectable CPC is similar to that of bone mineral, meaning it will be relatively insoluble at neutral pH and increasingly soluble as pH decreases. This is an important characteristic of normal bone mineral that facilitates controlled dissolution by osteoclasts as the cells causes a lowering of the pH at the site where bone will be dissolved.

Mechanical injection device

Currently available CPCs are mixed by hand and to be injected, the cement paste must be transferred into the appropriate delivery system, usually a syringe. Khairoun *et al.* (1998) defined “injectability” to mean the percentage by weight of the part of the amount of paste which could be extruded from such a syringe, either by hand or by force of 100 N maximum. The use of additives can decrease the extrusion force required for the cement paste. Modification of the injection device, such as shorter cannulas with a larger diameter, as well as small injection rates, favors a good injectability.

Particle size

Handling properties and tissue response are highly dependent on the setting reaction of the cement. The setting reaction is based on a dissolution-precipitation reaction and the entanglement of the precipitated calcium phosphate crystals, therefore particle size has an influence on the setting reaction. For example, the larger the particle size the smaller the surface area. A small surface area will slow the rate of dissolution, leading to a longer setting time. In this case, where this cement consists of multiple calcium phosphates – TTCP and DCPA, it is especially important to regulate the particle size since the balanced supply of Ca^{2+} and PO_4^{3-} is important for the precipitation of Hydroxyapatite. Both TTCP and DCPA can supply Ca^{2+} and PO_4^{3-} ions as shown in Eqs. 8 and 9 (Ishikawa, 2014).

Then Ca^{2+} and PO_4^{3-} are precipitated as hydroxyapatite crystals as shown in Eq. (10)

The overall reaction can be expressed as shown in Eq. (11)

However, TTCP and DCPA supply different Ca/ PO_4 molar ratios. TTCP which has a Ca/P ratio of 2.0 supplies a larger amount of Ca^{2+} for the formation of Hydroxyapatite which has a Ca/P ratio of 1.67. DPCA which has a Ca/P ratio of 1.0 supplies less Ca^{2+} for the formation of HA. Therefore, TTCP and DCPA should dissolve at the same rate for the formation of HA, however, if the particle sizes of both TTCP and DCPA are the same, the dissolution of each will not occur at the same rate. When the dissolution rates of TTCP and DCPA are compared, TTCP dissolves quickly, while the dissolution rate of DCPA is slow.

Table 5 summarizes the setting reaction of a TTCP/DCPA cement with their different particle sizes. As shown in this table, cement consisting of small TTCP and large DCPA does not set. The mechanical strength of the cement increases with increasing TTCP/DPCA particle diameter ratio. The cement with a large TTCP and a small DCPA results in the highest mechanical strength. Where small TTCP is combined with large DCPA, TTCP dissolves quickly as it has a larger specific surface area. Dissolution of TTCP supplies more Ca^{2+} ions and increases pH. At high pH, apatite is still the most stable phase, thermodynamically. However, too high a supersaturation results in the formation of amorphous calcium phosphate or small apatite crystals which are too small to interlock with each other, resulting in a lower mechanical strength. As mentioned previously, TTCP dissolves faster than DCPA,

Table 5 Setting reaction of a TTCP/DCPA cement with varying particle sizes

Average particle diameter (μm)		Ratio of the average particle diameter of TTCP/DCPA	Compressive strength (MPa)
TTCP	DCPA		
1.6	11.9	0.13	0 (no setting)
12.4	11.9	1.04	7.1 ± 1.0
1.6	0.9	1.78	21.8 ± 4.4
12.4	0.9	13.78	51.0 ± 4.5

Note: Ishikawa, K., 2014. Calcium phosphate cement. Ben - Nissan, B. (Ed.), *Advances in Calcium Phosphate Biomaterials*. Springer.

therefore, the combination of a large TTCP with a small DCPA is necessary in the formation of HA. The use of larger TTCP with smaller DCPA allows the appropriate amount of supersaturation and thus is the key to TTCP-DCPA cements.

The supply of Ca^{2+} and PO_4^{3-} by the dissolution of TTCP and DCPA results in a supersaturated solution with respect to HA. Therefore, Ca^{2+} and PO_4^{3-} are precipitated as HA crystals. The precipitation reaction results in the decrease of the Ca^{2+} and PO_4^{3-} concentration, which elicits further dissolution of the TTCP and DCPA. The dissolution-precipitation continues until all the TTCP and DCPA are consumed. The precipitated HA crystals interlock with each other to set and harden.

As previously mentioned, a reduction in particle size produces a significant decrease in both initial and final setting times and an acceleration of the rate of cement hardening or hydration of the curing. With a decrease in powder size, a significant increase in the rate of the reaction is observed (Ginebra *et al.*, 2004). According to Chow *et al.*, the optimum particle size for TTCP ranges from 1 to 80 μm with median = 17 μm approximately. DCPA powder should be in the range of 0.4–3 μm , with median = 1 μm approximately.

The particle size of the powder phase is a key factor that contributes to the cement properties and must be considered to optimize the cement for the given clinical requirements. Optimization and control of the particle size could avoid the need to incorporate other additives which may hinder the mechanical properties or potentially compromise the bone cement biocompatibility (Ginebra *et al.*, 2004). However, it is important to note that too fine a particle size has the potential to affect the product injectability due to thick paste formation.

The main ingredients of the calcium phosphate cement in this study are TTCP, DCPA and MCPM. As previously mentioned, TTCP powder is synthesized from a solid-state reaction between equimolar amounts of commercially available CaHPO_4 (DCPA) and calcium carbonate, CaCO_3 , which are mixed and heated at 1500°C for 6 h in a furnace followed by quenching at room temperature (Carey *et al.*, 2005). Typically, the mixture is ground and ball milled to obtain TTCP particles with sizes ranging from approximately 1 to 80 μm , with a median of 17 μm . DCPA powder is commercially sourced and has particle sizes ranging from 0.4 to 3 μm , with a median of 1 μm (Carey *et al.*, 2005). MCPM is also commercially sourced, however, being a highly soluble compound, the particle size of MCPM is not regarded as a critically important factor (Chow, 2008).

As DCPA is the least reactive of the compounds in the DCPA + TTCP reaction, it is desirable to use smaller DCPA and larger TTCP particles to ensure the reaction can proceed with the desired stoichiometry. Chow (2008), also noted that larger DCPA particles are not desirable as they do not have a sufficient surface area to match the high reaction rate of TTCP, leading to a large amount of unreacted DCPA in the system resulting in a product with a lower strength.

Reduction of the particle size can be achieved during reagent manufacture through the powder milling process, in turn resulting in an increased powder surface area. These modifications alter the surface area of the powder available for contact with the liquid, thus affecting the dissolution rate of the phosphate and calcium ions from the solid particles. This increases the reactivity rate of the CPC reagents, thus, decreasing the setting time and increasing cement hardening (Barralet *et al.*, 2002; Ginebra *et al.*, 2004; Bohner, 2007).

A more regular or equiaxed morphology particle has been reported to improve injectability and Ishikawa (2003) have observed that cements based on TTCP-DCPA-water mixtures were more injectable when TTCP particles were round and not irregular in shape although this morphology has a direct influence on the surface area.

Ginebra *et al.* (2004) investigated the influence of particle size on the final structure of the cement at the micro and nanoscale range with results showing that the higher specific surface area produced by the reduction in particle size, strongly accelerated the hydrolysis of the α -TCP into Ca-deficient HA. They also reported that the reduction of the particle size produces a substantial decrease of the setting time and accelerates the hardening of the cement without significantly affecting the final strength attained.

A decrease in particle size has also been reported to improve injectability and Ishikawa (2003) have observed that cements based on TTCP-DCPA-water mixtures were more injectable when TTCP particles were round and not irregular in shape. It is also desirable that the particles are deagglomerated to allow for an increased viscosity and improved injectability as the heavier agglomerated particles may cause blockages in the cannula during injection at the defect site.

In summary, the optimization of the particle size and specific surface area of the powder phase can vary the properties (setting time, hardness, morphology, porosity etc.) of the final cement product. Therefore, particle size is a crucial parameter in the development of a calcium phosphate based bone substitute and thus will be a major focus in the course of this project. Beyond Ishikawa *et al.*, there is very little published data on actual particle size.

Mechanical Properties

A limiting factor of calcium phosphate cements is their mechanical properties. They are very brittle and have low impact resistance and relatively low tensile strength. Porosity is one of the main reasons for their low strength. The presence of pores makes it easy for macro and micro cracks to propagate through the material, thus reducing the mechanical properties of the cement. Porosity may be controlled by adjusting the particle size and the powder to liquid ratio. On the other hand, a certain level of porosity is desired to allow for bone ingrowth into the set cement. Other factors affecting strength are the materials used in the solid phase, particle size, incorporation of filler materials in the solid phase, powder to liquid ratio, and various liquid phases. The theory behind the use of filler particles is that if a strong filler is present in the matrix, it may stop crack propagation. However, the presence of filler particles will reduce the porosity of the material and therefore, decrease bone ingrowth into the cement. A reduction in the bone ingrowth into the cement will lead to a slower resorption rate and thus slower bone substitution. The addition of polymers and composites to cement formulations has been tried in an attempt to increase strength which proved successful, however, the formation of HA was reduced thus leading to a reduction in the biocompatibility of the cement. Research shows that it is difficult to increase the strength of the cement without compromising its bioactivity. Target values for mechanical properties of calcium phosphate cements have not been determined. However, the targets would depend on the location of the cement in the body, the type of loading expected to be experienced by the cement, the type of bone into which it is placed and the amount and direction of the forces applied. In general, the mechanical properties of the cement should match those of the material being replaced.

Bone Void Filler Applications

Calcium phosphate cements are most commonly used to fill bone defects or voids. These may arise when large sections of bone have had to be removed (e.g., bone cancers) or when bone augmentations are required (e.g., maxillofacial reconstructions or dental applications). The bone filler is used to reinforce porous bone to give better support for screws and plates in fracture fixation. It can also provide a scaffold and encourage the rapid filling of the void by naturally forming bone and provides an alternative to bone grafts.

Calcium phosphate cements are promising materials for both dental and orthopedic applications due to their self-setting nature, mouldability, biocompatibility, lack of any by-products and their potential for being replaced by new bone. The ability to be molded in place is an important property of calcium phosphate cements due to the complexity of some bone defects/voids. The area of interest in this research is in craniomaxillofacial applications. The use of calcium phosphate cements in this area is logical as there is little or no stress generated in these conditions. The ability to mold the material during placement is advantageous for cosmetic reasons.

Premixed Formulations

Most of the currently available CPCs are in the form of a powder and a liquid that are mixed immediately before use. In the clinical situation, the ability of the surgeon to properly mix the cement and then place the cement paste in the defect within the prescribed time is a crucial factor in achieving optimum results. Thus, the need for a premixed cement paste is evident. A premixed cement paste would be stable in the package and harden only after being placed in the defect. This can be achieved by combining calcium phosphate powders with a non-aqueous paste. When this paste is placed into the defect diffusion of water from the surrounding tissues would cause the paste to harden and form a cement. However, this technique is not always suitable, for example, for large defects the amount of diffusion of water is not sufficient to cause hardening across the entire cross section of the defect/implant. To combat this issue, dual-paste premixed cement formulations were developed. Such a system can be devised by preparing a non-aqueous paste and an aqueous paste with calcium phosphate powders suspended in both pastes. The two pastes would be kept separate in the packaging. When the two pastes are mixed together in the defect, diffusion of water from the surrounding tissues and also water from the aqueous paste will cause the cement to harden. The dual-paste system hardens more rapidly and uniformly than the single-paste system due to the provision of water in the aqueous paste. In general, premixed calcium phosphate cements have lower mechanical properties, possibly due to the volume taken up by the non-aqueous liquid. Research and improvements on this aspect of premixed formulations are on-going.

Existing Products

Bone substitutes are being increasingly used in craniomaxillofacial (CMF) surgery. A wide variety of bone substitutes have been employed over the past 50 years. The three most common apatite forming cements used in the CMF area are Norian CRS (Synthes, Paoli, PA), BoneSource (Stryker, Kalamazoo, MI) and Mimix (W.Lorenz Surgical, Jacksonville, FL). A comparison of these cements is summarized in [Table 6](#). It is important to note that the compressive strength obtained for these products may not be comparable due to variance in compressive strength test methods which may result in an overestimation of the strength of the material.

Table 6 Comparison of the properties of calcium phosphate cements

	<i>Norian CRS</i>	<i>Bonesource</i>	<i>Mimix</i>
Base Component	MCPM, TCP, Calcium carbonate	TTCP	TTCP
Compressive Strength (MPa)	30	50	22
Resorbability	Complete	Minimal	Minimal
Pore diameter (μm)	0.03	0.002–0.005	211
Initial setting time (min)	10	10–15	3.4
Final setting time	1 h	4 h	4–6 min
Sets in a moist environment	Yes	No	Yes
Osteoconductive	Yes	Yes	Yes

Note: Pryor, L.S., Gage, E., Langevin, C.-J., *et al.*, 2009. Review of bone substitutes. *Craniofacial Trauma & Reconstruction* 2, 151–160.

Norian CRS Bone Cement™

Norian CRS bone cement is a pliable calcium phosphate cement that is mixed *in vivo* to form dahllite, a carbonated apatite, once set. Originally approved by the FDA for use in distal radius fractures (Pryor *et al.*, 2009), it has also been used broadly in craniofacial surgery. Norian CRS bone cement is prepared by mixing sodium phosphate solution with MCPM, TCP and calcium carbonate to form a bone putty. This putty begins to harden in 2 min during an exothermic reaction that may reach as high as 42°C and is set in 10 min. Maximum strength is not achieved until 24 h (Pryor *et al.*, 2009). In a recent study of Norian by Zins *et al.* reconstructed skull bone defects in sheep showed excellent osteointegration, but almost no osteoconductivity over the course of 12 months (Zins *et al.*, 2008). Drop tests resulted in fractures in the center of the construct rather than at the interface. Norian is slowly absorbed over time and is not intended for use in load-bearing areas.

Bone Source™

Bone Source is a self-setting calcium phosphate cement originally approved for use in filling burr holes and cranial defects well as the augmentation and restoration of bone contour in the craniofacial skeleton. It is prepared by mixing calcium phosphate salts including TTCP in a sodium phosphate buffer, forming a putty that remains malleable for approximately 20 min (Pryor *et al.*, 2009). Bone Source hardens into HA, and like other HA cements, is very slowly absorbed over time. It is not intended to fill defects over 25 cm² and lacks sufficient strength for load bearing applications.

Mimix Bone Void Filler™

Mimix, like Bone Source, achieved FDA clearance for use in filling burr holes and craniotomy defects and in smoothing facial skeleton contour abnormalities over a surface area no larger than 25 cm². The cement is prepared by mixing dry components of calcium phosphate powder, including TTCP, and sodium citrate dehydrate with an anhydrous citric acid solution. As it cures, Mimix hardens into HA and is mildly exothermic. Mimix Quickset is rapidly prepared, remains malleable for 3–4 min, and is completely set in 4–6 min.

HydroSet™

HydroSet is a calcium phosphate cement that comes in a powder and liquid form which is mixed and loaded into a syringe by the user. It is an injectable, sculptable and fast-setting bone substitute. Its design function is a fast-setting cement indicated to fill bony voids or gaps that are not intrinsic to the stability of the bony structure. HydroSet™ was specifically formulated to provide exceptional wet-field environment characteristics and remodels to natural bone through osteoclastic resorption and new bone formation. As HydroSet™ cement sets the reaction that occurs does not release any heat that could potentially damage the surrounding tissue thus increasing the products desirability.

HydroSet™ powder consists of three powder components: dicalcium phosphate dihydrate (DCPD) tetracalcium phosphate (TTCP), and tri-sodium citrate. And a liquid phase that is water based with polyvinylpyrrolidone (PVP), and sodium phosphate [Na₂HPO₄]. Once set, HydroSet can be drilled and tapped to augment the placement of provisional hardware. This powder and liquid requires mixing by the surgeon prior to use which introduces the possibility of inconsistent mixing by the surgeon and paste hardening/setting prior to insertion into bone defect.

Drawbacks of Existing Products

The main drawback associated with most of the existing products on the market is that, in clinical use, the surgeon needs to have the CPC powder and liquid mixed properly and thoroughly in a short period of time. The paste needs to be transferred into a

delivery device before it is injected into the defect before the paste hardens. The requirement of on-site powder-liquid mixing increases the time spent in surgery. It may also raise concerns about insufficient and inhomogeneous mixing, thus compromising the strength of the material, and inconsistencies between operators causing unpredictable variations. Also, over mixing after precipitation starts will lead to the breaking up of the interlocking structure which will compromise the mechanical properties. The surgeon must anticipate when wound closure is going to be required and call for cement mixing to commence approximately 7 mins prior to this point. If there is a delay in the anticipated closure time this may result in wasted material. To circumvent such problems, it is desirable to have CPC that are in the form of a dual-paste premixed self-hardening calcium phosphate cement system which is stable as provided but hardens only after being introduced to the bone defect and positioned properly. Such premixed types of product eliminate variability and also reduce time spent in the operating room.

Critical Assessment of Current Literature on Calcium Phosphate Cements

After reviewing the literature it became apparent that there are considerable differences in protocol when producing and analysing calcium phosphate cements.

Immersion Media

The immersion media used to store calcium phosphate cement samples varies greatly, some solutions include physiological-like solution (PLS), simulated body fluid (SBF), Tris buffer and deionised water. Each of these solutions will have a different effect on the immersed cements in terms of setting chemistry and reaction rate. PLS contains calcium and phosphate ions which will increase the reaction rate of a cement compared to the same cement immersed in an alternative media. SBF contains ions such as Mg^{2+} and Cl^- . Mg^{2+} has been shown to inhibit apatite formation (Giocondi *et al.*, 2010). The pH of deionised water may affect the reaction rate of cement samples also and does not adequately represent the conditions the cement would be exposed to in vivo. Tris buffer is a solution which does not contain any other ions which may interfere with the reaction rate of the cement but does not mimic the in vivo conditions as at the defect site, intraoperative levels of Ca^{2+} and PO_4^{3-} are non-zero, but are difficult to predict. PLS contains Ca^{2+} and PO_4^{3-} ions and can, therefore, represent in vivo conditions to some extent. For this reason, and for the purpose of comparison to literature, PLS, buffered to pH ~ 7.2 was the immersion media of choice used in this study.

Compressive Strength

Compressive strength measurement does not accurately represent the forces seen on the cement in vivo. Flexural strength may be a more appropriate technique to imitate the forces seen on the cement once implanted, but is difficult to measure due to brittleness and porosity of these materials. Another issue with compressive strength measurements is the tendency for researchers to manipulate their samples to give higher strengths. This is achieved by applying a load to the cement while it is in the mold, during setting, producing denser samples, thus, resulting in samples with a higher compressive strength when compared to samples which are simply loaded into the mold by hand. Applying a load to the cement while in the mold does not represent conditions observed by the cement in vivo. It is rarely outlined in publications whether or not a load was applied to the samples, making comparison difficult.

Characterization

Traditional methods of characterization of calcium phosphate cements include XRD, SEM and FTIR. A few studies have used ^{31}P MAS NMR to characterize cement phase but these are in the minority (Legrand *et al.*, 2009). There are a number of issues with relying on XRD for phase identification; due to the similarity of the HA and OCP crystal structure there is only one diffraction line different between the two phases. This line appears in OCP at $4.7^\circ 2\theta$. Many researchers scan from $10^\circ 2\theta$ and therefore miss this diffraction line, hence missing the presence of OCP. If an investigator does scan from $3^\circ 2\theta$ it is still possible that the OCP phase will be missed. This is because the plane associated with the 4.7° peak is so small it can easily be missed by the x-ray if the crystal is not in the correct orientation. Similarly with FTIR, many of the absorption bands for HA and OCP are very close or overlapping and make phase identification extremely difficult. Using optical methods such as SEM for phase identification can also prove difficult as there are many conflicting publications on the morphology of specific phases due to differences in formulation/production techniques.

Conclusions

Calcium phosphate cements have become established materials for clinical bone substitute and augmentation applications due to their key characteristic of presenting an osteoconductive interface to the native tissue and typically exhibiting an absence of foreign body response and fibrous encapsulation. Furthermore, such materials may exhibit bio-resorption in vivo with replacement by newly

grown bone. The rate and extent of this behavior is determined by both the chemistry of the CPC system (brushite forming cements show greater bioresorbability than HA forming cements) and also the anatomical site of implantation and the defect size. Pre-mixed dual paste type formulations offer superior handling and placement characteristics as well as more consistent homogeneity and thus more predictable properties in vivo, but generally at the expense of mechanical strength due to the presence of the suspension vehicle components of the paste systems. These dual paste systems also offer the potential for the addition of bioactive or pharmaceutical agents to the cement system which will be a focus for future development of these materials. Of continuing interest for the future is the development of formulations with unique properties tailored for specific anatomical sites/surgical techniques, and more generally efforts will continue to address their principal disadvantage and clinical limitation ie low strength and brittle behavior via the modification of formulations to a more composite nature via the incorporation of polymeric/bio-polymeric components aimed at conferring toughness and strength, yet retaining the osteoconductive properties and also the bio-resorption potential where appropriate.

Bone Regeneration With Ceramics Scaffold

Vida Strasser and Maja Dutour Sikirić, Ruđer Bošković Institute, Zagreb, Croatia

Introduction

The skeletal system is an elaborate structure built for movement and protection while simultaneously having a role in breathing, metabolism, cell production, and even sound transmission. These functions are highly specific and each one of them requires a specialized type of bones (Ott, 2017). All of them have the ability to constantly remodel themselves, which makes them capable to correct small injuries or defects, especially if the patient is young and healthy. Problems do occur in larger fractures and in older patients where the remodeling ability is diminished and the porosity of the bone is increased. Bone diseases commonly affect aging bone when systemic diseases like osteoporosis, osteoarthritis, or bone cancer/metastasis become more frequent. It is estimated that several hundred million people worldwide are affected by musculoskeletal conditions, making it a severe medical problem (Baroli, 2009). As a result, bone is the second most transplanted tissue after blood (Shegarfi and Reikeras, 2009), but the availability of bone transplants is limited, they are expensive and have several drawbacks. Therefore, the solution to this problem is sought in bone substitute/regeneration materials which can improve the outcome of the clinical treatment and ensure the long-term lifespan of the implant.

Bone Composition, Structure, and Mechanical Properties

From a materials science standpoint, bone can be considered an organic-inorganic composite with a complex, hierarchical structure. Bone biomineralization starts by osteoblasts secretion of an unmineralized organic matrix that will guide the mineral deposition, which will develop into hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, HA), a form of calcium phosphate (CaP). The complexity of bone structure is represented in **Fig. 1** where different levels of organizations are denoted. The first level represents the major components, i.e., collagen, HA, and water. Although more than 200 proteins can be found in the bone, about 90% of protein content consists of collagen type I, folded in a triple helix structure. Thin, small and plate-like nanocrystals of HA attach to these fibers (Weiner and Wagner, 1998). Fibers control the growth of the crystals and organize themselves in layers to form fibrils. As the crystals continue to grow, they compress the fibers and join in sheet-like form. These sheets can be parallel (lamellar bone) or cylindrical (osteon). Osteon is the basic structural unit of a bone structure and will form diverse microstructures, based on the location and the function of a bone. All osteoblasts found between the sheets will modify into osteocytes (bone cells involved in bone remodeling, signal transmission, and calcium removal) (Ott, 2017).

Cancellous (or trabecular, spongy) bone can be found as an internal porous structure for example in long bone ends or in the vertebrae. It is well vascularized and here the blood-forming (haematopoietic) occurs. The spongy structure also helps in the optimization of the bone weight and ease of movement, reducing stress caused by jumping or running. Cortical, more dense bone is usually surrounding the cancellous bone and provides a mechanically more robust structure, built for endurance ([Dorozhkin, 2012](#)).

The composition of mature bones varies depending on the bone type from about 50% to 90% mineral, 5% to 40% organic matrix, and 50% to 90% water (Boskey and Robey, 2013; Ott, 2017). As an essential part of our locomotive system, bones can on average withstand around 4 MPa stress during daily activities, with a mean load of a hip joint up to 3000 N (Dorozhkin, 2018a).

Bone Implant Materials

For the material to be successfully used in bone replacement or regeneration it should be: (Alvarez-Urena *et al.*, 2017; Shanmugam and Sahadevan, 2018):

- *Biocompatible* – non-harmful to the patient regarding its phases, surface properties, chemical reactions, mechanical load, and closeness of fit as well as non-immunogenic (without causing severe inflammation or implant rejection);
- *Bioactive* – able to bond directly to the bone and to form strong inosculation interface between a tissue and the implant which can resist a relative displacement between the two progressing bone formations and enhance the success rate of the restoration;
- *Osteoinductive* – able to trigger the start of bone regeneration by promoting the mitogenesis of undifferentiated mesenchymal cells, leading to the formation of osteoprogenitor cells that have the osteogenic capacity;
- *Osteoconductive* – able to direct bone growth by triggering fibrovascular tissue and osteoprogenitor cells invasion of a porous structure, often acting as a temporary scaffold, which will be replaced with a newly formed bone;
- *Biodegradable* – capable of being broken down into non-harmful products during the regeneration process in a proper period (which differs with the age of the patient).

Also, implant material must be sterile, should not trigger the development of teratomas or cancers, and can't be radioactive.

The surgical procedure of introducing new bone or substitute implant material into a defect, or around it, with the intent of helping bone healing is called bone grafting (Xiao *et al.*, 2013). Depending on the source of the bone grafts they can be classified as autografts, allografts, xenografts, and alloplastic grafts.

Autograft

Autograft (autologous or autogenous bone) is a bone tissue taken from the same organism in which it will be implanted. This material has native components and can promote healing by inducing cells to trigger new bone growth without the risk of disease transmission. Autograft can be utilized for relatively small procedures and it requires additional surgery, at a harvesting site that commonly stays painful after surgery. Further complications like infections, nerve injury, fractures, or hematoma are commonly associated with harvesting an autograft (Carlisle and Fischgrund, 2009).

Allograft

An allograft is a bone taken from one patient and placed into another one. There is no additional surgery for the same patient as in autograft, but allograft is not genetically identical, which can lead to immunogenic reactions and it presents a risk of disease transmission. This risk can be reduced with treatments like demineralization and lyophilization. Common complications associated with allografts are unwanted resorption, pain in the site of the repair, high rejection rate, prolonged inflammatory response, reduced biomechanical properties and greater variability than autograft (Carlisle and Fischgrund, 2009; Zhang *et al.*, 2019).

Xenograft

A xenograft is a material taken from one species and placed in another one, such as marine biominerals taken from corals or shellfish and used as a bone graft. Most commonly used xenografts are from a bovine or porcine bone that are lyophilized/demineralized and deproteinized before grafting. In comparison to the allograft, they are relatively inexpensive and readily available materials, but they still carry all risks of allografts, including ethical concerns. Furthermore, bovine xenograft degrades quicker than bone, induces a greater immune response and its osteogenicity is low (Dorozhkin, 2012).

Alloplastic Graft

Alloplastic (or synthetic) bone graft is made from synthetic materials. Such material is disease-free, there is no concern about immunological compatibility, it can be sterilized and is easily available (Dorozhkin, 2012). Examples of alloplastic grafts are diverse metallic or ceramics components, commonly shaped into some form of scaffolds.

Scaffolds

An optimal solution for bone regeneration is sought in scaffolds. Bone tissue scaffold is a 3D biomaterial that provides architecture and environment for bone tissue to develop and grow, guiding the spatially and temporally complex process of bone regeneration (De Witte *et al.*, 2018). 3D scaffolds should mimic the natural extracellular matrix (ECM) in its structure, surface topographies (from nano- to microscale), and mechanical properties (Wu *et al.*, 2014). They can also serve as carriers for different biologically active molecules, including growth factors, antibiotics, or gene therapy, among others (Kolk *et al.*, 2012; Roseti *et al.*, 2017).

To successfully perform their function, scaffolds need to fulfill several biological, mechanical, structural and technological requirements (Abbasi *et al.*, 2020; Amini *et al.*, 2012; Chen *et al.*, 2018; Darus *et al.*, 2018; De Witte *et al.*, 2018; Gittens *et al.*, 2014; O'Brien, 2011; Roseti *et al.*, 2017; Wu *et al.*, 2014):

- *Biological* – as all biomaterials, scaffolds should primarily be non-immunogenic, bioactive, biocompatible, and provide an environment in which cells can normally function (adhere, proliferate, differentiate, migrate, and produce new matrix). A scaffold should be biodegraded and synchronously replaced by newly formed tissue while providing enough mechanical support, and, when possible, release beneficial ions like calcium, strontium or magnesium, without toxic by-products. The rate of bone healing greatly varies with the age and health of the bone, so scaffold should be designed according to these conditions.
- *Mechanical* – scaffolds should mimic the mechanical properties of the bone as close as possible. Mechanical properties of scaffolds usually match the properties of human cancellous bone with compressive strength of 2–12 MPa and modulus between 0.1 and 5 GPa.
- *Structural* – scaffold should have an interconnected porous structure to enable proper cell growth and migration, nutrient flow, vascularization, and spatial organization, as well as interlocking between the scaffold and surrounding tissue which ensures long-term stable fixation of the scaffold. The recommended range for pore size is from 150 to 500 μm so osteoblasts can enter, nutrients and waste products can diffuse, while material integrity is not compromised. Overall porosity should be in the range 50% to 90%, which is challenging for the structure that needs to have great mechanical strength. A scaffold must be properly placed and fixated with the bone on the macroscale, which demands optimal properties of its surface (mechanics, porosity, grain size, roughness, chemistry, etc.) for the bone regenerative cells attachment and growth, i.e., for the onset of the new bone mineralization. At the microscale, the type of proteins that will adsorb will depend on the implant surface properties and can result in both, inflammation or healing. Those proteins will be recognized by the cell membrane receptors, which means that the implant surface must be precisely constructed since this can significantly influence the cell response. At the nanoscale, different features like nanopits, nanoislands, nanogrooves or nanotubes can significantly influence the cell response.
- *Technological* – for scaffolds to be successfully implemented in practice, all of their properties should meet corresponding regulatory requirements. The process of their production should be cost-effective and reproducible at a large scale. This also includes a sterilization procedure, i.e., it should be possible to sterilize scaffolds by usual industrial procedures. They also should be easy to handle in practice since complex preparation procedures should be avoided during operation. As well, they should enable a minimally invasive implantation procedure.

In the following articles materials and techniques used for bioceramics scaffold productions are presented.

Ceramics Materials for Bone Regeneration

Different materials are used for producing scaffolds, depending on their intended use. Metals are material of choice for load-bearing application. However, metals are not bioactive or biodegradable, they release toxic ions and are subjected to corrosion and wear. This commonly results in problems like dislocations or fibrous capsule production which can cause implant rejections (Ghassemi *et al.*, 2018). On the other hand, polymers have good biocompatibility and ductility, their bioresorption can be tailored, but their poor mechanical strength and degradation by-products can be a problem. Bioceramics are emerging as bioactive, biodegradable, and mechanically stiff materials that could overcome some of the difficulties of metals and polymers. However, they could have low strength and brittleness, as well as a slow degradation rate (Chocholata *et al.*, 2019).

In general, ceramics are considered as polycrystalline non-metallic inorganic materials with good compressive strength and inertness. Examples are silicates, metallic oxides, carbides, sulfides, refractory hydrides, selenides or natural structures like bone, teeth, etc. Bioceramics are ceramics specially developed for biomedical applications like bone fillers, implant coatings, scaffolds, etc. (Alvarez-Urena *et al.*, 2017; Xiao *et al.*, 2013). Like all ceramics, bioceramics are hard but brittle, wear-resistant, chemically stable, electrically, and thermally insulating. The key properties in which bioceramics differ between themselves are degradability and bioactivity (Xiao *et al.*, 2013). The first generation of bioceramics materials was developed to serve as a mechanical support for the damaged site. They are biocompatible but inert, so that material does not trigger an immune response, with major materials in use being alumina and zirconia (Yu *et al.*, 2015). The ability of some bioceramics (bioglasses, glass ceramics, HA) to stimulate bone regeneration and form a strong interface with the bone spurred the development of second generation of bioceramics, the bioactive and bioresorbable materials (Yu *et al.*, 2015). Bioactive materials are materials of choice for small defects or mechanically non-demanding bones (e.g., cranial) but their usage is limited by brittleness. Most recently, bioresorbable materials came to focus as the ideal substitute for the bone, since they do not just substitute but also regenerate the injured part of the bone. Such materials do not cause disease transfer or immunological problems and some can be used as drug-delivery systems. Unfortunately, their mechanical properties are weak, and their degradation rate is hard to predict (Dorozhkin, 2018b). Porous materials are more beneficial for cell attachment and growth, but their load-bearing ability is tenfold times lower than cancellous bone. Only ceramic materials that have similar values to the cortical bone is dense bioactive ceramics (Fig. 2(a)). This dense ceramics refers to HA with tensile strength ranging from 40 to 200 MPa and Young's modulus from 80 to 110 GPa, but its fracture toughness is low, approx. $1.2 \text{ MPa m}^{1/2}$ (Dorozhkin, 2012; Farid, 2019).

The third generation of bioceramics incorporates instructive cues for inducing favorable cell response. The examples are highly porous scaffolds or scaffolds loaded with cells, genes or growth factors (Yu *et al.*, 2015). Differences in ceramics bioactivity

Fig. 2 (a) Mechanical properties of biomaterials for bone tissue applications compared with properties of cortical and cancellous bone, (b) Bioactivity spectra of bioceramics implants: (1) relative rate of bioreactivity, (2) time dependence of bone bonding at an implant interface. are represented in Fig. 2(b) where relative bioreactivity (1) is correlated with the interfacial bond formation rate between implants and bone (2).

Bioinert Bioceramics

Bioinert bioceramics were used for the bone tissue replacement to produce load-bearing material that will serve to permanently replace bone. Bioinert bioceramics are considered as standard support for mechanically strenuous sites like hips or knees. Commonly used materials are alumina, zirconia, carbons, sintered HA, calcium alumina oxides, and silicon nitrides. Alumina ceramics is made from aluminum oxide (Al_2O_3) and commonly used in bioceramics, orthopedic and dental applications since it has a high hardness (> 20 GPa), corrosion resistance, and excellent wear, but it is brittle (Drouet *et al.*, 2017). Zirconia (ZrO_2) in its partially stabilized form is an alternative for alumina with better mechanical properties, making it highly usable as a dental implant material, especially as a composite with alumina, calcium oxide, magnesia or yttria, but its degradation can be problematic (Shanmugam and Sahadevan, 2018). Other commonly used bioinert ceramics for bone implants are silicon nitride or

diamond-like carbon, to name a few. The lack of bond formation between the tissue and bioinert ceramics materials can lead to a nonadherent fibrous capsule that causes loosening and implant failure (Hench, 1991). As a solution, materials with porous structures were suggested, where tissue can lock and bond with the implant. However, the porous structure has lower mechanical stability which leads to another set of problems to solve. Silicon nitrides and carbides have good mechanical properties and are nontoxic, but expensive to produce so currently their scaffolds are in the development phase (Drouet *et al.*, 2017).

Bioactive Bioceramics

Bioactive materials are chemically similar to the bone. This enables them to bond with the bone and trigger a natural repair mechanism of the bone tissue. Common bioactive ceramics are bioactive glass ceramics, HA, and calcium silicates. Bioactive glass can trigger new bone formation by releasing the calcium and phosphorus ions that can be utilized in a bone reconstruction procedure. It is used in larger cranial defects but it can also be shaped for use in a microsurgical environment for small bones like the middle ear or spine. However, particles or granules are preferred form which can be pressed into diverse shapes and used as fillers or spacers (Al Tamami *et al.*, 2020; Cottrill *et al.*, 2020; Drouet *et al.*, 2017). Since bioglass is unsuitable for load-bearing implants it is mostly used as a coating, for example of alumina hip joint cups or titanium alloys that usually increase osteointegration (Dmoušek *et al.*, 2012).

Most praised glass-ceramics is apatite-wollastonite (A/W) system (Cerabone®, Ceravital®) a combination of silica phosphate glass-ceramics that is biocompatible, bioactive and has a significantly higher toughness, strength, elastic modulus and stability so it can be used even in some load-bearing applications (Kokubo, 2008). Components like glass-ionomer cements (GICs) are commonly used as restorative materials in dentistry, for example as a composite of calcium-fluoroaluminosilicate glass particles and polyacrylic acid (Gremillard and Tadier, 2017). Such mixtures partially dissolve glass which releases ions and provoke cement forming in a matter of minutes.

HA has an optimal chemical composition, but its brittleness is much higher than the bone due to the lack of organic matrix, especially if it is used in the porous form (Karageorgiou and Kaplan, 2005).

Bioresorbable Bioceramics

The most advanced approach is to use resorbable implant materials that can biodegrade in a time needed for natural bone tissue to regenerate and replace the implant. The distinction between bioactive and bioresorbable bioceramics is sometimes in their structure: dense HA is bioactive and will last for 5–7 years in the organism, while porous HA will be resorbed within 1 year (Goto *et al.*, 2001; Raucci *et al.*, 2016). The rate of biodegradation is hard to accurately control because the resorption rate depends on diverse factors. Also, the strength of these materials is commonly insufficient to produce sufficient support during the regeneration procedure.

The most investigated bioresorbable bone substitute materials are different forms of CaPs, tunable osteoinductive and osteoconductive materials that are easy to produce (Drouet *et al.*, 2017). Commonly used forms are tricalcium phosphate (TCP, $\text{Ca}_3(\text{PO}_4)_2$), calcium-deficient hydroxyapatite (CDHA, $\text{Ca}_{10-x}(\text{HPO}_4)_x(\text{PO}_4)_{6-x}(\text{OH})_{2-y}$, $0 < x < 1$), HA, and bi- or triphasic CaP (diverse combinations of TCP and HA). TCP-based ceramics (both α - and β -form) are often used as coatings on metallic prostheses, dental restorative materials, or small bone replacements. β -TCP is among the most frequently used bone substitutes in orthopedics and dentistry since it is bioresorbable in comparison to the HA-based ceramic. Biphasic calcium phosphate ceramics and triphasic ceramics are slowly replacing the use of β -TCP in Europe and are commonly referred to as calcium phosphate ceramics (Dorozhkin, 2016).

Another material that encourages bone regeneration and serves as a temporary bone substitute is calcium sulfate hemihydrate (CS, plaster of Paris / gypsum). CS is already used as injectable repair for smaller bone defects (Kelly and Wilkins, 2004). Calcium carbonate from organisms like corals can also be used for conversion to carbonate apatites, as an osteoconductive material with a structure similar to trabecular bone. Unfortunately, it has reduced biodegradation and mechanical properties, while the availability of the corals also remains a challenge (Damien and Revell, 2004).

Bioceramics in Organic-Inorganic Composites

The bones' exceptional properties are a consequence of them being organic-inorganic composites. In an effort to mimic the bone to a higher extent, organic-inorganic composites consisting of bioceramics and polymers are being developed. Such materials utilize the advantages of both classes of materials (osteoconductivity and sustained release of bioceramics, tailored degradability and controlled release of polymers) while minimizing their drawbacks. Structure and volume ratio of polymers and arrangement of bioceramics within polymer matrix are key parameters that enable tailoring of composite properties. Among the most investigated composites are those with poly(α -hydroxy ester)s and copolyesters of the lactic and glycolic acid, collagen and gelatin (Alvarez-Urena *et al.*, 2017).

Scaffolds Processing Techniques

Several techniques can be used to produce ceramics scaffolds with different structural features. Generally they are divided into conventional and additive manufacturing techniques.

Conventional Techniques

Conventional techniques are based on a top-down approach, starting from large solids and fabricating them into smaller, complex objects. Complex porous 3D structures are especially demanding to produce by conventional techniques and often the control of pore architecture is not satisfactory (Butscher *et al.*, 2011).

Principles of some of the most commonly used conventional techniques are:

- *Solvent casting and particulate leaching* – thick paste, consisting of water soluble porogen (i.e., salt), ceramics powder, and organic solvent or polymer solution is poured in a mold and left to dry. Porogen is leached by keeping the scaffolds in water for a specific period. After leaching, the scaffold is sintered to obtain mechanical strength. The control over pore size is achieved through the size of porogen particles (Darus *et al.*, 2018; Roy *et al.*, 2017).
- *Thermally-induced phase separation* – the slurry is prepared by mixing the ceramics powder with a dioxane/water mixture. Frequently, a polymer is added to the slurry. The slurry is heated to 15–20°C above the determined cloud point and then quenched at the desired water bath temperature. To obtain a porous structure, the sample is freeze-dried and subsequently sintered. Scaffolds with anisotropic pore structures, tubular morphology and porosity up to 95% are obtained (Roy *et al.*, 2017). The scaffold porosity can be controlled by freezing rate, temperature, and polymer concentration (Thavornmyutikarn *et al.*, 2014).
- *Polymer bead* – polymer beads of specific sizes are mixed with ceramics powder and compacted. Obtained samples are heated at around 550°C to burn off the polymer and subsequently sintered at higher temperatures. The pore size is controlled with the size of polymer beads. (Roy *et al.*, 2017).
- *Freeze casting* – a stable aqueous ceramics slurry containing appropriate dispersant and binder amounts is prepared and unidirectionally frozen to obtain a solid 3D component. Water is removed by freeze-drying to retain the scaffold's shape and integrity. The dried scaffold is sintered. (Darus *et al.*, 2018; Roy *et al.*, 2017).
- *Gas foaming* – in situ gas-forming agent is added to the stable ceramics slurry which is cast to the desired geometry. During the setting, formed CO₂ gas escapes the system and this creates interconnected pores in the ceramics. This technique was developed to avoid organic, cytotoxic solvents (Roseti *et al.*, 2017; Roy *et al.*, 2017).
- *Sol-gel technique* – this technique is based on the polymerization of metal aloxides. The precursor is mixed with water to form sols through hydrolysis and condensation. Addition of surfactants and catalyst results in foaming of the sol and beginning of condensation. Foamed sols are transferred to the molds and turned into gel after sealing for a while. Thermal treatment densifies the matrix (Zhu *et al.*, 2020).
- *Gel casting* – fluid and castable slurry is prepared by dispersing ceramics powder in an aqueous solution of monomer, cross-linker, free radical initiator and catalyst. The slurry is poured in a mold and in situ polymerized gel forms which immobilizes ceramics particles in the shape of the mold. Still wet object is removed from the mold and dried in controlled conditions. An obtained dry green body is strong enough to be machined. Binder is removed by heating and the sintering is used to improve mechanical properties (Yang *et al.*, 2011).
- *Electrospinning* – electrospinning is a technique for producing nanofibrils of different materials. The method is based on electrostatic repulsion between the surface charges to form a nanofiber. A drop of solution or a melt is held at the end of the capillary by its surface tension. Applying a high electrostatic voltage results in distortion of the drop into a conical jet. When the voltage becomes high enough a stable liquid jet is ejected from the tip of the cone. It dries during the jet traveling in the air, and ultra-fine fibers with a high surface-to-volume ratio are formed and collected on electrically grounded targets (Balu *et al.*, 2014).
- *Sacrificial mold* – polymer foam is coated with ceramics slurry and the polymer is removed by suitable heating (Roy *et al.*, 2017).

Advantages and disadvantages of these methods are given in Table 1, while examples of the scaffolds produced by these methods are given in Fig. 3.

Additive Manufacturing

With conventional techniques, it is not always easy to achieve strict control over pore size, interconnectivity, and geometry. This in turn means, that scaffolds produced in that manner cannot specifically and adequately improve cell growth and tissue regeneration (Ma *et al.*, 2018). Additive manufacturing (AM, sometimes called rapid prototyping) techniques offer a solution to this problem.

Additive manufacturing is a family of technologies capable of generating 3D objects directly from digital data (Parra-Cabrera *et al.*, 2018). The core concept of all of these technologies is the rapid and seamless transition between a computer model and its physical realization (Gibson *et al.*, 2010). Commercial AM technologies create a 3D object by depositing multiple 2D layers on top of each other. They differ in materials that can be used, how layers are formed, and ways of their bonding (Parra-Cabrera *et al.*, 2018).

AM methods have overcome limitations of conventional bioceramics processing methods in control of the shapes, geometry, and internal architecture of the scaffolds, without the usage of toxic organic solvents. A scaffold is made by deposition of overlying layers which enables stricter control of porosity, pore size, and mechanical properties. These methods also enable the preparation of scaffolds with two or more materials. Combined with medical imaging of the place of injury they enable the production of scaffolds matching the specific patient's needs (Hammel *et al.*, 2014; Roseti *et al.*, 2017). Also, these techniques enable the design of the personalized scaffold structure matching the surrounding tissue of the specific patient and accounting for the differences in

Table 1 Comparison of advantages and disadvantages of conventional ceramic production techniques

Technique	Advantages	Disadvantages
<i>Solvent casting and particulate leaching</i>	● simple production ● easy method ● control of pore size and porosity	● toxic solvent and porogen residue ● decreased activity of bioinductive molecules ● no pharmacological agents can be added ● weak mechanical properties
<i>Thermally-induced phase separation</i>	● anisotropic pore structure with tubular morphology ● high porosity (up to 95%) ● control of pore size and structure ● low probability of the defects	● complex and expensive processing ● poor mechanical properties ● not suitable for seeding cells or bone tissue growth (pore sizes 10 – 100 μm) ● use of organic solvents
<i>Polymer bead</i>	● simple inexpensive process	● small scale production ● poor mechanical properties ● unable to form complex geometry
<i>Freeze casting</i>	● high mechanical strength ● environmentally friendly	● a complex process requiring special and costly instrumentation ● poor control over pore geometry and distribution ● long processing time
<i>Gas foaming</i>	● inexpensive process ● no organic cytotoxic solvents ● good for preparing large samples ● eliminates the use of chemical solvents	● a complex process ● poor mechanical properties ● limited dimension accuracy ● possibility of closed pore structure ● poor control over pore size, distribution, and interconnectivity ● restrained inclusion of cells and bioactive molecules
<i>Sacrificial mold or powder</i>	● a simple and inexpensive process ● good control over pore interconnectivity	● poor compressive strength
<i>Sol-gel technique</i>	● highly mesoporous structure ● high purity ● low cost	● poor mechanical properties ● large content of nanoporosity
<i>Gel casting</i>	● near-net shape ● high homogeneity ● good interconnectivity when combined with foaming	● slurry rheology and homogeneity
<i>Electrospinning</i>	● large surface areas ● superior mechanical properties ● large scale production ● very thin fibers ● simple and inexpensive technique	● inadequate control of scaffold architecture, pore network, and size ● suboptimal 3D scaffolds ● organic solvents may be required ● limited mechanical properties

tissue structure connected with age, health, or the condition of the surrounding bone (Hammel *et al.*, 2014). AM methods may be applied directly from intended ceramics materials or indirectly using molds. Principles of the most frequently used AM methods are described below, while the main advantages and disadvantages of different AM techniques are given in Table 2.

Direct techniques utilize ceramics powder, colloidal solution, or paste to directly build the desired structure. The benefit of these techniques is that powder bed supports successive layers, due to which spanning elements are more easily fabricated. Among most commonly used techniques are (Bose *et al.*, 2015; Hammel *et al.*, 2014; Parra-Cabrera *et al.*, 2018; Roseti *et al.*, 2017):

- **Stereolithography** – is a 3D printing technique based on the selective solidification of photopolymer resins using a UV light source. 3D objects are processed by subsequent deposition of 2D layers which are solidified either by scanning a laser over a surface of the resin or by projecting the entire slice. For manufacturing ceramics objects, photopolymerizable suspensions of ceramics powders are used. After creating a green part (the part before sintering), a cross-linked polymer binder is burned-out and the remaining object is sintered to improve mechanical properties. To prevent crack formation, deformation, or shrinkage caused by polymer removal the cured ceramics green part must have density 50% or higher.

- *Extrusion based methods* – a movable extrusion head is used to selectively deposit material to form layers. An example of this technique is robocasting which was originally developed for ceramics materials. In robocasting, a highly concentrated suspension of the material of interest and a solvent are deposited layer-by-layer through a syringe-type nozzle. Ensuring adequate viscosity of suspension enables that layers keep their shape until drying. When printing ceramics, the dried object is usually heated to remove additives and to increase mechanical stability. Fused deposition modeling works in the same manner, the difference being that a thermoplastic polymer is extruded through a heated nozzle. Fused deposition of ceramics is the modification of this method used to process 3D ceramics structures. It uses thermoplastic polymer mixture, which includes a binder, plasticizer, and dispersant, as a ceramics powder carrier. Using multiple extruders in parallel enables incorporating different materials in different parts of the object, with a discrete transition between materials.
- *Powder bed-based methods* – manufacturing starts by spreading a thin layer of powder (around 100 μm thick) across the building area using a counter-rotating leveling roller. Layers are created by selectively binding particles in the powder layer. Binding of ceramics powders is usually done by selective deposition of the liquid binder by inkjet printhead. Alternatively, a dry binder can be mixed with the powder, and binder activator is printed. After printing ceramics objects are usually heated to evaporate binder and to sinter the object. The first commercial powder bed-based method is selective laser sintering. This method uses a high-power laser to fuse powder particles in thin layers that are built on top of each other. Before laser sintering, the powder is preheated just below the melting/transition point to minimize thermal distortion and facilitate the fusion of the new layer to the previous one. The focused CO_2 laser beam is directed on a power bed in the pattern according to CAD design. Surrounding powder remains loose and serves as a support for the subsequent layer. After one layer is processed, the platform is lowered and the next layer of powder is spread until the desired object is made.
- *Inkjet 3D printing* – binder jetting machine distributes a layer of powder onto a platform. Subsequently, liquid droplets of bonding agent are deposited onto the powder by inkjet printer, bonding the particles together. After the layer is finished, the platform is lowered and the next layer is produced. 3D printing can be also used to print sacrificial mold, in this way aqueous binder can be used and porogen size is not limited. However, limitations are high density packing of porogen in complex features and restrictions on the shape or feature design.
- *Bioprinting* – small units of cell and biomaterials are dispensed together with micrometer precision to form tissue-like structures. Extrusion-based and laser-based bioprinting can be used for producing ceramics or composite scaffolds. In extrusion-based bioprinting continuous filaments of material are dispensed using a piston or pneumatic pressure to fabricate 2D or 3D structures. Laser-based bioprinters use a pulsed laser to transfer materials to a receiving substrate.

Examples of the scaffolds produced by AM are given in Fig. 4.

Drawbacks of direct methods are that the feature size is limited by the resolution of the machine, scaffold material must be compatible with AM process and sometimes smooth surfaces are created which do not provide a good environment for the cells. Also, liquid or powder residues may be left behind in the scaffold and the size of the printed components may be restricted due to the lack of strength (Hammel *et al.*, 2014). A possible solution is indirect technique. A mold of negative architecture is made of polymer or wax by AM. The ceramics slurry is cast into the mold which is removed by heating. The remaining ceramics scaffold is then sintered to the required density.

Advanced Applications of Scaffolds

Expanded interaction surfaces of porous implants are built for the flow of nutrients and cell attachment, but they can be loaded with diverse substances and used for targeted delivery with prolonged release of e.g., particles, therapeutics, polymers, or even living cells. The active components can be delivered in various forms, from powders, granules, spheres, pastes, fibers, tubes, and

Table 2 Features of different additive manufacturing techniques

Technique	Parameters	Advantages	Disadvantages
<i>Stereolithography, SLA</i>	● layer thickness: 1 μm for specimen volume < 35 mm^3 ● smallest feature indirect 366 μm, direct 1 – 70 μm	● high accuracy ● complex 3D structures ● easy removal of photopolymer by heating ● fine control over pore size and shape	● photo-polymerization of materials ● photocurable materials ● expensive materials and equipment ● support material needed ● slow process ● extensive and laborious postprocessing ● toxic uncured resins ● difficult to fabricate larger scaffolds with complex internal structure
<i>Fused deposition modeling, FDM</i>	● layer thickness: 250 – 370 μm ● smallest feature rod diameter 260 – 700 μm	● high porosity ● complete pore interconnectivity ● control of pore size ● macro-shape control ● no support material needed ● no residual powder ● good compressive strength ● solvent-free	● high processing temperature ● limited variety of materials ● pore inconsistency ● thermoplastic polymers required ● mechanical anisotropy
<i>Selective laser sintering, SLS</i>	● layer thickness: 76 – 100 μm ● smallest feature 45 – 100 μm	● complex structures ● independent control of porosity and pores size ● wide range of materials ● solvent-free ● no support material needed ● good mechanical properties	● high processing temperature ● limited to small pore sizes ● low accuracy ● high cost ● low surface quality ● low mechanical strength ● slow printing speed ● powder residue ● toxic organic solvent ● low mechanical strength ● limited to small pore sizes ● low surface quality ● risk of entrapment of unbound powder ● low accuracy ● difficult depowdering process
<i>3D printing</i>	● layer thickness: slurry 20 – 100 μm, dry powder 50 μm ● smallest feature 350 – 500 μm	● easy process ● high porosity ● independent control of the size of the pores and porosity ● macro shape control ● wide range of materials ● no support material needed ● possibility of printing without sintering ● cost efficient	● high processing temperature ● limited to small pore sizes ● low accuracy ● high cost ● low surface quality ● low mechanical strength ● slow printing speed ● powder residue ● toxic organic solvent ● low mechanical strength ● limited to small pore sizes ● low surface quality ● risk of entrapment of unbound powder ● low accuracy ● difficult depowdering process
<i>Robocasting</i>	● layer thickness: 225 – 750 μm ● smallest feature rod diameter 200 – 400 μm	● high accuracy ● no support material needed ● combination of materials possible ● simple and economic ● no entrapment of particles into pores ● high fabrication speed ● applicable to a wide range of bio-ceramics	● material limitations ● slow process ● expensive process ● geometry restricted ● low accuracy ● limited to logpire structures ● easy to sag and collapse during printing ● precise control of rheology required

wires to films, coatings, hydrogels, or whole blocks, combined into innovative biomaterials that can advance bone regeneration process. They can be added into the finished porous scaffolds, deposited on its surface, or integrated into the scaffold during its formation. The combinations of two or more of these options are common. Fig. 5. summarizes most used substances that can be integrated with bone regeneration scaffolds.

Scaffolds With Particles

Biodegradable CaP and silica-based scaffolds release ions like calcium or silicone which can stimulate osteoblasts to increase bone growth. This beneficial effect can be enhanced by the incorporation of ions like lithium, silver, strontium, magnesium, etc., in the scaffolds. Such substitutions also influence the degradation rate, mechanical and biological properties like antibacterial activity

Fig. 4 Additive manufacturing techniques for ceramics scaffold production: (a) calcium phosphate (CaP) ceramics printed using stereolithography-based additive manufacturing (b) polycaprolactone – tricalcium phosphate scaffold printed using fused deposition modeling, (c) (CaP)/poly(hydroxybutyrate-co-hydroxyvalerate) scaffold fabricated using selective laser sintering, (d) 3D printed hydroxyapatite scaffold, (e) glass scaffold printed using robocasting, (f) porous bioprinted scaffolds containing mesenchymal stem cells and ceramic particles with plasmid DNA encoding BMP-26. (Bose *et al.*, 2013). Alternatively, particles of titanium, alumina, iron oxide, silica, or carbon (graphene) can also be used to tune ion release and/or to improve the mechanical properties of the scaffolds (Canal and Ginebra, 2011). Apart from different composition, nanomaterials of different morphologies can be used (Erceg *et al.*, 2020).

Fig. 5 Schematic representation of substances commonly integrated into bone scaffolds. The main components for integration are diverse particles. From ions and nanoparticles to mesoscale spheres or carbon nanofibers, therapeutics (diverse drugs, hormones, growth factors or genes), polymers (natural or synthetic) and cells (mostly diverse forms of stem or progenitor cells).

Scaffolds With Therapeutics

Drug release scaffolds

Scaffolds can also serve as a structure that can co-deliver substances like drugs, supplements or growth factors. This enables local regulation of pain or reduction of the infection at the site. Delivery of different drugs like bisphosphonates, aspirin, ibuprofen, gentamicin, vancomycin, methotrexate, cisplatin, doxorubicin, gentamicin sulfate, cefoperazone sodium and flomoxef was tested (Habracken *et al.*, 2007; Porter *et al.*, 2009; Rödel *et al.*, 2018). Commonly used carriers are mesoporous silica, silica-based glasses, CaP beads or coatings, injectable CaP, TCP/alginate beads, injectable HA, or gypsum, silicon dioxide, etc. All these materials are used to encapsulate drugs and to prolong their release. Drug release depends on the composition of the inorganic phase, its porosity, specific surface area, topography, degradation rate, etc. (Dorozhkin, 2018b; Rödel *et al.*, 2018). Furthermore, it is possible to utilize glass-ceramics in processes like localized heating aimed to destroy malignant tumorous cells which, in comparison to the classical treatments, have minimal damage to the rest of the body (Wang *et al.*, 2017). However, the homogenous drug loading is a challenge, as is controlling the rate of simultaneous drug release. Common problems are burst release in the first hours or days after the surgery (that could cause overdosage), the release of drugs by both diffusion and degradation (that causes problems with determination of appropriate dosage), degradation of an active ingredient during processing, etc. (Parent *et al.*, 2017). The resorption rate must be comparable with the specific bone regeneration rate, which can spread from a few months up to 2 years (Dorozhkin, 2018b). In the meantime, the scaffold must endure all mechanical stresses that the bone in question is normally enduring.

Growth factors

Growth factors such as bone morphogenetic proteins (BMPs), transforming growth factor (TGF) and insulin growth factor (IGF) were tested in diverse bone defects with good results regarding the accelerated bone defect filling, resorption of the implant and bone remodeling in general (Arcos and Vallet-Regí, 2013; Shi *et al.*, 2020). They also stimulate cell recruitment and differentiation and are currently used in treatments, but not without the concerns (Shi *et al.*, 2020). Observations of long term effects on patients suggest the possibility of some factors like BMPs to produce tumors, immune responses, infections, etc. Therefore, caution with dosage is recommended (Schmidt-Bleek *et al.*, 2016). Loading of growth factor into bioceramics scaffolds can be achieved by physical entrapment and nanoparticle encapsulation (De Witte *et al.*, 2018).

Hormones

Osteoporosis is more common in women after menopause because estradiol activity is lowered. This hormone affects mineral resorption and bone loss, so targeted delivery of estradiol using diverse bone scaffolds improves bone formation (Cinebra *et al.*,

2006; Shi *et al.*, 2020). Similar results were obtained with prostaglandin and parathyroid hormone that both stimulate bone formation but could increase the risk of later cancer development. Mesoporous materials, like mesoporous silicas, are considered as good materials for both hormones and growth factors delivery (Vallet-Regí and Ruiz-Hernández, 2011).

Gene therapy

Gene transfer technology includes application of nucleic acids for therapeutic purposes. Research is focused on RNA interference-based therapy (to replace pathogenic genes) or replacing growth factors/hormones with genes (that will encode for these factors). They are usually based on the release from different polymer matrices or particulate ceramics containing gene vector complexes. For example, a combination of chemically modified mRNA (encoding for BMP-2 protein) and biphasic calcium phosphate granules (Balmayor *et al.*, 2016). Unfortunately, in this stage of research high dosages are required which causes safety and immunogenic concerns (Dang *et al.*, 2018; Shi *et al.*, 2020).

Scaffolds with polymers

Scaffolds with polymers commonly include both natural and synthetic polymers, or their combinations. The most used natural polymers are proteins (collagen, albumin, elastin, silk fibroin, fibronectin, osteocalcin, etc.) and polysaccharides (gelatin, chitosan, alginate, cellulose), while synthetic degradable polymers commonly include polylactic, polyglycolide or poly(lactic-co-glycolic) acid, polycaprolactone and their diverse combinations in a form of copolymers (Bharadwaz and Jayasuriya, 2020; Garg *et al.*, 2012). They can be combined with materials like nanoparticulate CaP or silica-based materials into nanocomposites and serve as injectable nanofillers or part of the scaffold coatings (Bharadwaz and Jayasuriya, 2020).

Proteins like collagen, osteocalcin, sialoprotein, and osteopontin have a good affinity for calcium ions and can interact with HA where they can regulate the formation and growth of the crystals (Shi *et al.*, 2020).

Because of versatility, storage capacity, and good bioactivity of the polymers, the most probable solution to the controlled release of therapeutics will be ceramics scaffolds combined with polymers. With the proper setup of their properties (e.g. porosity, charge, strength, bioactivity, biodegradability or cell adhesion) drug release could be much better regulated (Ghassemi *et al.*, 2018; Polo-Corrales *et al.*, 2014).

Scaffolds with living cells

Novel studies are focused on the implantation of scaffolds with cells (freshly isolated or cultured), implantation of tissues grown in vitro from cells and scaffolds using donor cells, or direct implantation of a scaffold that will simulate body to promote local repair. Nanoparticulate form of bioactive ceramics is popular for these scaffolds because, in that form, they can easily be combined with living cells. The activity of cells can be modulated with the modification of scaffold nanotopography (Zhu *et al.*, 2020). The nanostructures that can be used for better bone remodeling should have following properties: the grains below 100 nm in size, the boundaries of the grains enhance cell adhesion, differentiation and growth. Such nanoceramics have outstanding physical, chemical, and mechanical properties and are easily shaped. This is especially interesting in combination with titanium, silver, aluminum or HA nanoparticles that exhibit antibacterial activity, enhanced adhesion of osteoblasts, and lower the adhesion of fibroblasts (which favor fibrous encapsulation) (Affatato *et al.*, 2006; Wagner *et al.*, 2006; Webster, 2001).

Combining CaPs with different reinforcement agents and cells from the human body could produce material that can satisfy most of the above-listed demands. For example, resorbable CaP scaffolds seeded with cells, or stem cell bi- and tri-culture are of great significance in the regeneration of dental, craniofacial and orthopedic defects in clinical practice (Lin *et al.*, 2019a; Wang *et al.*, 2014).

Scaffolds Which Introduce Stimulus

Materials that can exhibit different physical stimuli that could enhance tissue repair and regeneration are lately coming into the focus.

Graphene and its derivatives (graphene oxide, reduced graphene oxide, carboxyl graphene oxide), carbon nanotubes and quantum dots are non-degradable materials which, in addition to conductivity, possess excellent thermal, mechanical and optical properties. Initially, they were used to enhance mechanical properties, but presently their conductivity is investigated for enhancement of tissue regeneration. However, no conclusive results can be found about their cytotoxicity and their ultimate fate in vivo (Aslankoohi *et al.*, 2019).

Magnetic bioceramics show great potential as devices for bone healing and on-demand release of drugs or biomolecules using ferrimagnetism, ferromagnetism or superparamagnetism (Xu and Gu, 2014). If magnetic mesoporous silica or HA doped $\text{Fe}^{2+}/\text{Fe}^{3+}$ materials are used, the local increase in temperature can be achieved, that will destroy cancerous cells, while producing minimal (and often temporary) damage to surrounding body cells (Drouet *et al.*, 2017; Tampieri *et al.*, 2012).

Implantation of scaffolds can disturb natural signaling pathways due to their rigidity for signal conduction. Piezoelectric materials capable of generating and transferring the signals according to the changes in their environment are emerging as a possible solution (Jacob *et al.*, 2018). Numerous piezoelectric materials are available, while in bone tissue engineering only particulate form of piezoelectric barium titanate, boron nitride or zinc oxide had stimulating effects without significant problems regarding toxicity (Aslankoohi *et al.*, 2019; Jacob *et al.*, 2018).

Conclusion and Future Directions

Bioceramics scaffolds are promising materials for enhancing our abilities to repair bone tissue. A variety of materials and methods available for producing these scaffolds offer a wide range of possibilities in treating rather complex diseases and traumas. For example, the damage caused by cancer can be overwhelming for the organism to cure by itself, but using early detection methods and quick reaction with appropriate medical implants that can simultaneously cure and replace damaged tissue offer new hope to many patients. Several challenges remain to be solved to fully exploit the advantages of bioceramics scaffolds. Extended life expectancy of the population increases the severity of premature implant failure. The problem of resistant bacterial strains significantly affects implantation procedures and the solution for successful infection control still needs to be found. Mechanical properties of ceramics are still an issue, especially for biodegradable materials which require to retain needed mechanical support while being degraded and replaced with the new bone. With further development, trauma patients could have a better recovery rate with less pain and inflammations due to the locally delivered drugs, and even without the need for a second surgery for implant removals.

Exciting new fields where bioceramics scaffolds have high potential are personalized medicine and development of nanoceramics. In personalized medicine living cells are combined with the ceramics scaffolds. Stem cell research in this field has already provided good results in *in vivo* experiments. Nanoceramics research is focused on providing a suitable nanoscale environment for cells to further enhance bone growth with appropriate material for fast bone regeneration.

Constant advances in manufacturing technologies, especially additive manufacturing, are enabling that such advanced materials more successfully reach medical practice.

Advanced Processes for the Design of Customized Ceramic Medical Devices

Eric Champion and Patricia Pascaud-Mathieu, University of Limoges, French National Centre for Scientific Research, Institute of Research for Ceramics, Limoges, France

© 2021 Elsevier Inc. All rights reserved.

Introduction

Various materials have been used to treat musculoskeletal deficiencies for more than 50,000 years of human existence. The early ones were aesthetic or functional devices designed to repair cranial injuries, replace teeth or limbs (Pietrzak, 2008). The first known ceramic medical device could refer to a toe prosthesis worn by a 3000-year-old Egyptian woman (Wagle, 1994). Today, autograft is considered as the gold standard in bone surgery. But, its harvesting can induce medical complications such as pain or infections (Heary *et al.*, 2002) and it may even be impossible due to limited available amounts, possibly not sufficient for defect filling, or insufficient quality. Besides, the architectural design, shape and size, of such implants are often unsatisfying because it cannot be adapted to the bone defect. To overcome these drawbacks and limitations, there is a growing demand for synthetic bone graft substitutes that may be customized on demand. Among the materials used, a first generation of biocompatible ceramic for medical devices appeared from the early 1960s, mainly made of alumina and/or zirconia. These ceramics present a high chemical and biological inertia associated with specific properties such as high strength, hardness and wear, and friction resistance. They can be used as load-bearing implants. Twenty years later, a second generation of medical ceramics arose, essentially made of calcium phosphates, which interacts with the surrounding living tissues and presents superior biological properties of bioactivity or bioresorbability. These two generations of ceramics are commonly used in a wide range of applications for bone tissue repair in orthopedics, maxillofacial surgery and dentistry. Nevertheless, there is an increasing need for advanced customized devices to treat various osseous pathologies for which there is still no fully satisfactory solution at present. This is particularly the case of the repair or reconstruction of large bone defects resulting for trauma, infectious diseases, cancer, or malformations.

Thus, ceramics are the subject of continuous efforts of research and development to extend their medical applications. The primary role of ceramic bone graft substitutes is to restore the injured function: food grinding, locomotion, protection of vital organs, etc. In addition to this fundamental role, two kinds of customizations can be highlighted.

- (1) The bone repair and regeneration itself, which requires the production of 3D scaffolds with complex tailored architecture. This architecture must include a network of interconnected pores at the microscopic scale (size < 1 mm) allowing the scaffold colonization by newly formed bone tissues. This approach directs to bone tissue engineering and regenerative medicine.
- (2) In some situations, aesthetic criteria have to be taken into account, such as in dental applications or for cranio-maxillofacial implants, for which the macroscopic design of the prosthesis has to be defined according to an individualized approach, which directs to personalized medicine.

Therefore, a multiscale approach to design advanced ceramic devices is required. To this end, emerging computer aided design and computer aided manufacturing (CAD/CAM) of ceramic parts appears to be the only technologies that can be implemented (Champion *et al.*, 2017). Conventional ceramic processing techniques suffer from limitation or inability to produce near-net-shape parts with highly complex design. Thus, the development of customized ceramics is a great challenge to provide new high-performance medical ceramics and extend their fields of applications to improve healthcare of populations. This chapter focuses on the main approaches implemented for the shaping of such advanced bioceramic devices.

Digital Manufacturing Processes: Towards Automization of Customized Fabrication

Digital manufacturing systems have been developed from the early 1950s for aerospace and automotive applications. Developments in the biomedical field began during the 1980s. CAD/CAM of customized ceramic devices involves three fundamental steps (Fig. 1): (1) acquisition of patient images of the pathological tissue using various imaging or scanning technologies (e.g., optical images, magnetic resonance imaging, computed tomography...), (2) transformation of images in digital data using a CAD software allowing 3D reconstruction and manipulation of data to simulate the medical device and set up of a digital file (e.g., Standard Tessellation Language – STL – file), to order the manufacturing machine, (3) shaping of the ceramic part by CAM using the processed data.

CAD/CAM can be applied to quite any ceramic part production using either subtractive machining (SM) or additive manufacturing (AM) technologies. Subtractive manufacturing technologies are based on the fabrication of a part by removing matter from bulk material. They have been widely used to produce metal or polymer parts and much less so for ceramic ones, mainly because of their high brittleness. Since the 1980s, new technologies of additive manufacturing appear. AM, in opposition to SM, is a process of joining materials to make parts from 3D model data, usually layer upon layer (ISO/ASTM, 2015). AM technologies were also developed initially to produce metal or polymers prototypes or parts. Some of these AM technologies, detailed above, have been adapted to shape three-dimensional ceramic parts from those set up for polymers or metals (Chartier *et al.*, 2015). The main subtractive and additive digital manufacturing technologies are summarized in Fig. 2.

Fig. 1 Flowchart of CAD/CAM of a ceramic medical device.

Fig. 2 Main manufacturing technologies. Reproduced from Galante, R., Figueiredo-Pina, C.G., Serro, A.P., 2019. Additive manufacturing of ceramics for dental applications: A review. Dent. Mater. 35, 825–846. Copyright © 2019, with permission from Elsevier.

In the medical field, the use of SM to shape ceramic parts is almost restricted to the dental field. AM is more generally investigated and applied in all areas of bone surgery, including orthopedics and maxillo-facial surgery. This chapter will be more specifically devoted to these AM technologies for the processing of ceramic medical devices. A very short focus will be dedicated to SM and AM for dental applications.

Four main AM technologies implementing CAD/CAM approach can be used to produce complex 3D ceramic parts (Chartier *et al.*, 2015). They have become of an increasing interest due to the wide possibilities they offer for the on-demand fabrication of customized implants for bone repair or scaffolds for the emerging bone tissue engineering. These technologies are particularly adapted to the rapid production of devices for personalized medicine. Thus, the contribution of the biomedical field to AM applications is strong with about 17% share in 2016 (Javaid and Haleem, 2018).

Whatever the AM technologies, the use of a STL file format, defined as a "file format for model data describing the surface geometry of an object as a tessellation of triangles used to communicate 3D geometries to machines in order to build physical parts" (ISO/ASTM, 2015), is required in order to facetize the CAD model so that it can be processed by the digital tools dedicated to additive manufacturing (Chartier *et al.*, 2018). The CAD design of the implant is sliced into 2D layers of the desired thickness, then imported into the additive manufacturing system. Finally, implants or scaffold with patient-specific geometries and/or

Fig. 3 Schematic depiction of the major AM technologies used to produce customized ceramic medical devices. Reproduced from Trombetta, R., Inzana, J.A., Schwarz, E.M., Kates S.L., Awad, H.A., 2017. 3D printing of calcium phosphate ceramics for bone tissue engineering and drug delivery. *Ann. Biomed. Eng.* 45, 23–44. Copyright © 2016, with permission of Springer Nature.

controlled multi-scale porosity are shaped layer-by-layer. The AM technologies used, for ceramic parts shaping are detailed in **Fig. 3**. They are classified in four categories according to the feedstock and the working principle: stereolithography (SLA) or vat photopolymerization, selective laser sintering (SLS) or powder bed fusion, robocasting (RB) or material extrusion and three-dimensional printing (3DP) or binder jetting (Brunello *et al.*, 2016; Champion *et al.*, 2017; Huttmacher *et al.*, 2004; Melchels *et al.*, 2010; Mota *et al.*, 2015; Trombetta *et al.*, 2017; Zocca *et al.*, 2015).

The resolution that can be achieved with these different AM technologies is superior to 500 μm , stereolithography having the best resolution (**Fig. 4**). This makes possible the achievement of personalized implants with sufficient dimensional precision but also of scaffolds containing pores with typical size of about 500 μm to allow new bone tissue ingrowth in the porous network of the scaffold.

Customized Bone Graft Substitutes and Scaffolds for Bone Tissue Engineering

A brief overview of the four most commonly used AM technologies, i.e., SLA, SLS, RB, and 3DP, is described hereafter and examples of bioceramic implants or scaffolds are provided. For each technology, illustrations of recent advances in printed bioceramic devices and their targeted medical applications are listed in **Table 1**. For further reading, a brief review, not reproduced here, listing a table of 40 chronologically arranged primary applications of additive manufacturing as used for medical purposes can be found elsewhere (Javaid and Haleem, 2018).

Vat Polymerization

Vat polymerization, also known as "stereolithography" (SLA), is an AM process based on the photopolymerization of selected areas of a photo-curable ceramic suspension (i.e., containing ceramic powder and a mixture of photosensitive monomers), previously spread on a building platform by way of a scraper, by applying a low-power ultra-violet (UV) light source or a laser beam (Chartier *et al.*, 2015). Once a layer of suspension exposed to beam becomes hardened according to the geometric patterns defined by the 2D slices of the CAD file, the subsequent layers are sequentially cured and linked together to form a solid green part.

		(Castilho <i>et al.</i> , 2017)	
	BCP (biphasic calcium phosphate)	(Castilho <i>et al.</i> , 2014)	Bone tissue engineering
	Functional graded scaffolds of Al ₂ O ₃ /Y-TZP	(Gingter <i>et al.</i> , 2015)	

The consolidated part thus shaped, unpolymerized suspension is removed and further thermal treatments of debinding and sintering are required to obtain a dense ceramic part.

The accuracy of SLA directly relates to the beam size. But, a highly focused beam that has to scan the surface to be polymerized on each layer would increase significantly the processing time so that scanning methods generally use beam larger than 100 µm in diameter. Such a resolution is sufficient to produce customized devices at the macroscopic scale to match the defect size and individualized aesthetic criteria but lacks of precision to develop scaffolds which porous architecture must be tailored at the microscopic scale. To overcome this limitation, integral microstereolithography (µSLA) method, derived from stereolithography, can be advantageously implemented (Bertsch *et al.*, 2003; Chartier *et al.*, 2015). In this case, the surface that must be polymerized can be integrally irradiated by a UV light that passes through a dynamic mask produced by a digital micro-mirror device (DMD) and reproducing the 2D pattern of the CAD slice. This method allows to increase the resolution without time consuming consequence.

Applications

The possibilities for using SLA method have particularly emerged for biomedical applications (Melchels *et al.*, 2010) but it is still mainly focused on polymer models fabrication (D'Urso *et al.*, 2000; Provaggi *et al.*, 2017; Sodian *et al.*, 2002). Indeed, direct shaping of ceramic parts by vat photopolymerization remains a difficulty because it requires specific suspension formulation containing high amount of ceramic powder and having specific rheological behaviour. The scattering of incident photons of the ceramic particles

Copyright © 2016, with permission from Elsevier.

reduces the resolution. To overcome these difficulties linked to the presence of a high amount of ceramic particles, indirect AM can be implemented. The approach is to shape a “negative” sacrificial polymer mould of the ceramic part, usually by SLA or 3DP, and to cast the ceramic suspension in this mould. Further heat treatment to burn the mould and sinter the ceramic part is applied (Skoog *et al.*, 2014; Charbonnier *et al.*, 2016; Chu *et al.*, 2001). Nevertheless, vat polymerization has been the first implemented AM to produce directly commercially available calcium phosphate bioceramic devices by for bone repair. Example of large craniofacial implants made in hydroxyapatite is given in Fig. 5. Such implants are produced using CAD/CAM from patient scanner (Brie *et al.*, 2013). Their “lace-like” periphery allows to match the bone defect and to have a close contact with the native bone tissue of the patient. One of the major difficulties in the production of large size and complex shape devices is to control and take account of the deformations and shrinkages that will occur during the post-sintering of the part in order to design and shape the green part at the required dimensions. Additional cylindrical macropores (Fig. 5(b)) or about 500 μ m in diameter are produced on the periphery of the implant, while the implant core is much thicker and fully dense to preserve good mechanical properties on the long term. After implantation, these macropores are colonized by newly formed bone, which results in a perfect osseointegration of the implant.

Concerning these macropores, reaching a high resolution to design their geometry is all the more important because cell behaviour is known to depend of the surface topography of the scaffold through curvature driven growth (Bidan *et al.*, 2013). Following the works of Bidan *et al.* (2013) on the influence of surface curvature, various scaffold designs have being investigated including graded porosity (Petit *et al.*, 2017), or different pore shapes and hierarchical structures (Guyot *et al.*, 2014; Gariboldi and Best, 2015; Ma *et al.*, 2018). A reliable production of model scaffolds by μ SLA with high dimensional resolution that takes account of the phenomenon of overcure due to light scattering and of the shrinkage of ceramics during post-sintering has been developed (Lasgorceix *et al.*, 2016). It permits to reach a dimensional precision of about 20 μ m and the design of pores with complex geometries (Fig. 5(c) and (d)). Investigation of bone cell colonization and vascularization of these macropores showed that the geometry of pore cross-section affected greatly the biological behaviour (Magnaudeix *et al.*, 2016; Rüdrieh *et al.*, 2019). Concave surfaces and angles associated to triangular or rhombus cross-sections greatly enhanced bone cell colonization, vascularization and blood vessels guidance (Fig. 6). Comparatively, convex angles or circular geometries were much lesser colonized and square cross-sections were the worse probably due to their long flat surfaces.

Powder Bed Fusion

Powder bed fusion is defined, in ISO/ASTM (2015) standard, as an AM process in which thermal energy selectively fuses regions of a powder bed. Among powder bed fusion category, Selective Laser Sintering (acronym SLS) process is the most widely used

Fig. 6 (A) In vitro colonization of Si-HA scaffold macropores by MC3T3-E1 pre-osteoblast cells after 7 days, (B) Ex ovo analysis of blood vessel colonization in Si-HA scaffolds. for developing bioceramic scaffolds. SLS is based on the formation of a ceramic part by applying a heating source, usually Nd:YAG or CO₂ laser beam with a wavelength suitable for the chemical composition of the raw material (Ferrage *et al.*, 2017), on selected areas of ceramic powder bed, previously spread on a building platform through a roller, to build each layer by sintering. The local powder densification can be done by directly sintering the ceramic powder. However, due to the low adsorption of ceramic materials at the wavelength of classical laser sources, SLS is more frequent performed on a blend of the ceramic powder with a binder phase which is melted by the laser source. The ceramic parts thus shaped, the unbound powder is removed and a post-consolidation process of sintering at high temperature is required to achieve fully densified ceramic devices.

Applications

Concerning bioceramics, only some works report the use of an experimental SLS system to fabricate bioceramic devices made of the most used ceramic materials: zirconia, alumina (Ferrage *et al.*, 2017) or hydroxyapatite (Cruz *et al.*, 2005) or biphasic calcium phosphate (BCP) (Shuai *et al.*, 2013). The low number of available studies can be explained by the challenging to fuse ceramic particles together by a laser beam. In fact, as mentioned above the use of a thermoplastic polymer functioning as a binder material is suggested to able the ceramic powder fusion (Duan *et al.*, 2010; Eosoly *et al.*, 2010). Barlow and Vail (1994) have also patented a shaping method based on an indirect SLS technique to produce ceramics parts from polymer-bound alumina. This alternative, called iSLS for indirect SLS (Deckers *et al.*, 2014) consists of mixing “sacrificial” polymer binder with ceramic powder allowing the “glueing” of ceramic particles together during the laser scanning before being burned during a debinding thermal cycle. The resulting ceramic part is then sintered. For example, Tang *et al.* (2011) used a slurry composed of alumina powder coated with PVA to produce dense bioceramic parts more easily (Table 1).

In the context of bone tissue engineering, iSLS method has been employed by some groups (Table 1) to develop directly composite materials composed of a biocompatible polymer matrix and hydroxyapatite filler, including PEEK (poly(ether-ether-ketone)) (Tan *et al.*, 2003), PVA (poly(vinyl alcohol)) (Chua *et al.*, 2004), PCL (poly(ϵ -caprolactone)) (Wiria *et al.*, 2007), or HDPE (high-density polyethylene) (Salmoria *et al.*, 2013). The biocomposite blend of PVA/HA were for example dedicated to craniofacial and joint defect applications (Chua *et al.*, 2004) whereas pure polymer material was preferred to produce lower stiffness scaffolds with high resolution for soft tissue engineering applications such as cardiac tissue (Chia and Wu, 2015).

The fabrication of designed porous biodegradable intervertebral fusion cages has been the subject of particular attention by for reducing revision spinal surgeries in order to avoid post-operative complications. 3D printed bioresorbable cervical cages (Knutsen *et al.*, 2015) and lumbar cages (Kang *et al.*, 2013) have thus been produced using SLS method with PCL/HA mixture. An example of composite scaffold produced by SLS is given in Fig. 7. Though the resolution of SLS is good enough at the macroscopic scale to produce personalized implants, one of its main limitation is the relatively low accuracy at the microscopic scale, which unlike μ SLA, does not allow the design of complex pore shapes for the production of bioceramic scaffolds (see Figs. 5 and 7).

Material Extrusion

According to ISO/ASTM (2015), material extrusion is defined as AM process in which material is selectively dispensed through a nozzle or orifice. Among the material extrusion process, robocasting (RB) method based on robotic deposition of a viscous paste by means of continuous extrusion through a nozzle onto a construction platform is the most commonly used for ceramics shaping. This method, unlike AM technologies mentioned above, does not require a post-shaping step of feedstock removing. In fact, green bodies can be directly debinded and sintered to consolidate the scaffolds. Through RB, ceramic scaffolds can be built up with good mechanical characteristics. However, the accuracy remains conditioned by the diameter and the geometry of the nozzle, which are restrictive parameters. Moreover, material extrusion can only produce “continuous” rods that do not allow the shaping of very complex geometries. Hence, this AM process has been not largely preferred to design scaffolds with tailored architectures.

Applications

Some research groups have lately implemented and developed the fabrication of tailor-made calcium phosphate ceramic parts by extrusion techniques based on HA and/or β -TCP slurries (Dellinger *et al.*, 2007; Simon *et al.*, 2007; Martínez-Vázquez *et al.*, 2010; Michna *et al.*, 2005; Miranda *et al.*, 2006) in particular for orthopaedic applications due to their potential in load-bearing bone tissue engineering applications (Miranda *et al.*, 2008). Example of scaffold that can be produced by RB is given in Fig. 8.

Binder Jetting

Binder jetting is defined, in ISO/ASTM (2015) standard, as an AM process in which a liquid bonding agent is selectively deposited to join powder materials. Binder jetting technology also known as “three-dimensional printing” (3DP) or “direct ink printing” (DIP) is based on the printing of a pattern by selective deposition of liquid binder solution droplets, through a print-head, onto a thin layer of powder, previously spread by roller, thus binding the particles together. The surrounding unglued powder, serving as support, is then removed and the remaining green part is consolidated at high temperature to obtain a dense ceramic body.

Applications

In the field of ceramic medical devices, some specimens have been built using powder-binder systems from calcium phosphate powders.

Seitz *et al.* produced HA scaffolds by jetting different nature of polymeric binder fluids to bond calcium phosphate particles, hydroxyapatite (HA) and/or tricalcium phosphate (β -TCP), together. Water soluble polymer blend (Schelofix) (Leukers *et al.*, 2005; Seitz *et al.*, 2005; Warnke *et al.*, 2010), water-based polymer binder solution (Fierz *et al.*, 2008), or an aqueous PVA solution (Irsen *et al.*, 2006) was used in these cases. 3D printed tricalcium phosphate tissue engineering scaffolds were also shaped with commercial organic water based binder (Fielding *et al.*, 2012; Tarafder *et al.*, 2013).

Gbureck *et al.* (2007) focused their works on the fabrication of calcium phosphate implants by printing process which consisted of a hydraulic setting reaction with a mixture based on phosphoric acid as liquid printing phase. By this way, brushite (DCPD), hydroxyapatite (HA) (Barralet *et al.*, 2009; Gbureck *et al.*, 2007), biphasic calcium phosphates (BCPs) ceramics containing hydroxyapatite (HA), and tricalcium phosphate (TCP) in varying ratios (Castilho *et al.*, 2014) and tricalcium phosphate (TCP) (Castilho *et al.*, 2017) scaffolds were shaped to substitute complex bone defects. For example, tricalcium phosphate scaffolds were developed to design resorbable cages (Fig. 9) for tibial region (Castilho *et al.*, 2017).

In terms of biomedical applications, another fabrication strategy was implemented by Gingter *et al.* to shape functionally graded system made of bioinert and/or bioactive ceramics. Their works focused on the production of innovative structures based on $\text{Al}_2\text{O}_3/\text{Y-TZP}$ by direct inkjet printing. The structures were built by means of two independently thermal printheads, one dedicated to alumina ink and the other one to yttria stabilized zirconia. Thus, DIP technology allows for creating graded ceramic bodies with varying material composition in several directions.

Dental Applications

CAD/CAM was implemented first, more than 25 years ago, in dentistry for the production of various fixed prosthetic restorations and has become a well established technology commonly used in this medical field (Lee and Lee, 2017). The main requirements for such applications are presented in Fig. 10. They include chemical inertia, mechanical reliability and durability associated with aesthetics criteria. During the past, according to the criteria, porcelain-fused-to-metal was considered as the standard for dental restorations. Nowadays, the demand for more aesthetic led to the production of all-ceramic restorations and the main ceramic materials commonly used to this purpose (Fig. 11) are resin matrix ceramics, silicate ceramics, alumina or zirconia (Conejo *et al.*, 2017).

CAD/CAM dental devices are usually produced by subtractive manufacturing (Fig. 1) based on milling of pre-sintered or fully sintered blocks mostly using 3–5 axis systems (Galante *et al.*, 2019). The advantage of sintered blocks is that the device can be milled directly at the final dimensions, which is generally the case except for alumina and zirconia. For these later oxides, pre-sintered blocks are used because they would be too difficult to machine after full sintering due to their very high hardness. This method requires that the shrinkage occurring during post-sintering treatment must be taken in account in the initial size and design of the milled part. These CAD/CAM technologies are now commercially available for the production of dental devices at the level of the chairside in a dental practice so that they can be widely spread (Blatz and Conejo, 2019). The main drawbacks of subtractive technologies relates to the processing cost of the manufacturing units and milling tools and to the waste of material upon machining (Azari and Nikzad, 2009).

Additive manufacturing (AM) technologies may constitute an alternative to overcome these problems and produce at lesser cost (Javaid and Haleem, 2018; Silva *et al.*, 2017). However, probably due to the difficulties linked to the direct shaping of ceramics by AM, few works have been devoted to these new approaches. Only 11 original research papers were published up to now (source Scopus, July 2019, using the following keywords: “additive manufacturing”, “dentistry” and “ceramic”). Attempts to

shape zirconia crowns (Fig. 12) by 3D printing (Ebert *et al.*, 2009; Emre *et al.*, 2012; Li *et al.*, 2019) have been made but difficulties remain to produce reliable ceramic parts without defects (large processing flaws, cracks, ...) so that improvements are required in view of reliable processing (Alghazzawi, 2016).

Concluding Remarks

CAD/CAM technologies appear promising to produce custom-made ceramic medical devices for personalized medicine or bone tissue engineering. These versatile technologies appear of particular interest to this niche market but there are few commercially available products. Several points can be put forward to explain these current limitations and challenges remain in the future developments of ceramic medical devices (Singh and Ramakrishna, 2017).

- The technologies themselves remain young and under development. Research effort and improvements, mainly in the feed-stock and process parameters to ensure a reliable and cost-effective production, are still a necessity. This is noticeably the case of for the production of mechanically resistant ceramic devices for load-bearing applications.
- The biological behaviour at the interface materials/living tissues must be better understood to provide rational of scaffolds design. The current trends include the use 3D bioreactors and cell co-cultures to provide a more physiological model than the classical 2D static cell cultures (Champion *et al.*, 2017). At the scientific research level combined approaches, especially by implementing AM manufacturing and biofabrication are also rising to improve the biological performances of implants and scaffolds (Giannitelli *et al.*, 2015).
- A wide variety in the protocols, formulations, procedures either in the processing or in the characterizations of devices under development can be found in the available literature so that it is difficult to acquire reliable knowledge. Thus, there is a crucial need for rationalization with approaches including standardizations and certifications. Finally, as it has been the case in

dentistry with CAD/CAM subtractive manufacturing of restorative dental devices, CAD/CAM to produce customized implants or scaffolds for bone tissues surgery will have to reach hospital centers and the surgeons to get involved in the designing for additive manufacturing (Gibson and Srinath, 2015). These last points appear to be key factor to achieve in the transfer of these technologies from research to viable end-user applications.

Introduction

Polymer-based biocomposites are a fundamental class of materials developed in the course of the past decades in response to the need for novel biomaterials that could be used in diverse biomedical applications, from orthopedic fixation devices to engineered scaffolds for the growth of cells and tissues (tissue engineering) (Boccaccini *et al.*, 2010). Although these materials find application in several fields of life sciences, in this chapter the focus will be on their use in tissue engineering (Gritsch *et al.*, 2017), with particular emphasis on the regeneration of bone (Amini *et al.*, 2012; Ning, 2016).

Tissue engineering (TE) is an interdisciplinary field that combines know-how from materials science, chemistry, biology and medicine to create artificial constructs, named “scaffolds”, that are able to support the regeneration of tissues while being gradually eroded and resorbed (Gough and Boccaccini, 2007; Hutmacher, 2006; Henkel *et al.*, 2013). TE represents a complex challenge that requires the fine tailoring of numerous parameters in order to create a functional interface between the artificial construct (scaffold) and the body (Gritsch *et al.*, 2017; Hutmacher, 2006). A candidate material for tissue engineering scaffolds has to fulfill several key physicochemical and biological requirements: it has to be biocompatible and non-immunogenic, have adequate mechanical properties to match the target tissue, exhibit porous structure to facilitate cell invasion and vascularization and be suitable for sterilization (Henkel *et al.*, 2013). But most importantly, especially in the case of bone, it has to have two key properties: controlled biodegradability (Van De Velde and Kiekens, 2002) and bioactivity (Kokubo and Takadama, 2006; Maçon *et al.*, 2015).

The chief difference between tissue engineering and conventional medical approaches is moving from what is called a “replacement” strategy, in which a medical device aims to restore a severed tissue only in its function but not its physiology, to a “repair and regeneration” approach, whose goal is to temporarily restore function to allow the defective tissue to regenerate and reestablish a physiological-like situation both morphologically and functionally (Henkel *et al.*, 2013). In this sense, biodegradability is an essential feature of scaffolds: regeneration cannot be achieved using materials that once implanted will permanently remain within the body (Van De Velde and Kiekens, 2002; Basnett *et al.*, 2017). Tissue engineering scaffolds shall be designed using mainly biodegradable materials, and biodegradable polymers in particular (Van De Velde and Kiekens, 2002; Rezwan *et al.*, 2006). Biodegradable polymers are a specific class of polymers with a tailorable ability to be progressively broken down by living organisms and environmental conditions *in vivo* (Hutmacher, 2006; Basnett *et al.*, 2017). In particular, if the degradation by-products are compounds that can be processed and eliminated through physiological pathways, the polymer will be deemed bioresorbable (Li, 2017). For instance, polylactic acid is broken down by hydrolysis into lactic acid moieties that can be readily converted into CO₂ by the Krebs cycle (Vert *et al.*, 1992). In general, there are several ways biodegradability can operate, mainly through hydrolytic, temperature-mediated, radiation-mediated and enzymatic degradations (Van De Velde and Kiekens, 2002). In a typical *in vivo* scenario, scaffolds will be mostly degraded by hydrolysis and enzymes (Vert *et al.*, 1992; Nelson and Cox, 2004): accurate material design will allow control over these phenomena and the development of a construct that has matching degradation and tissue in-growth rates (Hutmacher, 2006; Henkel *et al.*, 2013). In this way, the scaffold is effectively removed by the body while new tissue is forming (Fig. 1).

Filler candidates for the fabrication of composites for tissue engineering must possess another important biological property that is in fact tightly linked to their biodegradability: bioactivity. Bioactivity (or bioreactivity) is defined in this context as the ability of a material to successfully interact and bond with a target living tissue (Maçon *et al.*, 2015; Hench, 2015; Hench *et al.*, 1971). The term gained importance starting from the late 1960s, when it was first linked to the interesting properties of a novel class of materials: bioactive glasses (BGs) (Jones, 2013). BGs are a family of inorganic materials with several different compositions, most of which are able to create a strong bond with bone thanks to their ability to dissolve *in vivo* and to form hydroxyapatite, the natural mineral phase of bone on their surfaces (Jones, 2013). As a consequence, although the definition of bioactivity does not mention specific target tissues and a bioactive material could have properties that go beyond its ability to mineralize, the term “bioactivity” is still associated to the ability of a material to trigger biomineralization (Mahabadi and Alexandru, 2006; Miguez-Pacheco *et al.*, 2015). This verbal ambiguity is an interesting topic of debate and it was discussed in a recent review paper (Mahabadi and Alexandru, 2006). In this chapter, we will still refer to bioactivity in bone-specific terms as the ability of a material to trigger the deposition of hydroxyapatite either *in vivo* or in simulated body fluid (SBF) as an acellular bioactivity test (Kokubo and Takadama, 2006; Maçon *et al.*, 2015; Fujibayashi *et al.*, 2003).

Since most polymers available for biomedical applications lack intrinsic bioactivity (Rezwan *et al.*, 2006; Gritsch *et al.*, 2019), exception made for some natural polymers, e.g., silk-derived proteins (Marelli *et al.*, 2012b; Griffanti *et al.*, 2019), the idea of combining a biodegradable and often bioresorbable polymeric matrix with a bioactive inorganic filler is naturally an ideal and straight-forward approach to obtain a biomaterial combining biodegradability and bioactivity (Boccaccini *et al.*, 2010; Rezwan *et al.*, 2006; Baino *et al.*, 2015). The preparation of composite is achieved either by solvent-based or melting-based mixing of a bioactive

Fig. 1 The concept of regenerative medicine and the key elements for successful bone tissue engineering. Figure adapted from reference Hao, Z., Song, Z., Huang, J., *et al.*, 2017. *Biomater. Sci.* 5, 1382–1392, with permission of RCS publishing.

filler of desired size and aspect ratio (e.g., particles, fibers) with the biodegradable matrix polymer (Chen *et al.*, 2008), as identified more than 15 years ago (Rezwan *et al.*, 2006). The final properties of the composite will be a complex combination of the ones of the two materials. They depend on several factors, including filler homogeneity and size, interface properties between the two phases and filler-to-matrix ratio (Rezwan *et al.*, 2006; Chen *et al.*, 2008). The underlying relationship between these properties and the overall physicochemical and biological behavior of the final material is subject of study within the theory of composites material, as discussed in-depth elsewhere (Milton, 2002). Polymer-based composites with bioactive fillers as TE scaffolds are considered as an alternative to current therapies for bone reconstruction, which heavily rely on autologous tissue (Amini *et al.*, 2012; Henkel *et al.*, 2013). Autografts are well-studied and effective, but suffer from a number of disadvantages, mainly their limited availability and the need for invasive harvesting (Campana *et al.*, 2014). Polymer-based biocomposites have been long studied as a promising alternative to autografts and a possible solution to keep up with the increasing annual demand for bone grafts: for instance, bone disorder-related annual costs are expected to hit \$2.5 billion this year in the USA (Amini *et al.*, 2012).

This chapter offers an overview on traditional and recent materials and technologies developed for the production of bioactive and biodegradable polymer-based composites for bone tissue engineering. The most important bioactive glasses and bioceramics, as well as relevant polymers used in the field, will be listed and described in terms of properties, advantages and disadvantages. The most widely studied and promising approaches to process such composites and to fabricate them into scaffolds will be then outlined, from traditional protocols of particulate leaching all the way to the most cutting-edge techniques, such as bioplotting or 3D melt electrospinning writing. The development of nanocomposites will be also discussed highlighting the advantages of nanostructured composites. Recent relevant investigations and the most promising organic/inorganic combinations will be highlighted and discussed with special attention to their clinical translation potential, limitations of current technologies and possible directions for future developments.

Bioactive Ceramic Phases

Among other beneficial properties (e.g., mechanical properties enhancement), the filler phase in biocomposites has the main role of providing bioactivity to the system (Baino *et al.*, 2015; Milton, 2002). As previously discussed, bioactivity is defined in this case as the ability of a material to successfully bond to bone tissue by promoting biomineralization (Hench, 2015; Hench *et al.*, 1971).

In this section, the two main groups of bioactive fillers used in biomedical composites will be discussed: calcium phosphates (Ambard and Mueninghoff, 2006; Rahaman, 2014) and bioactive glasses (Jones, 2013; Rahaman, 2014; Rahaman *et al.*, 2011). Due to their similarity to the inorganic component of bone, the most common bioactive ceramics used in clinical applications are inspired by calcium phosphates (CaPs) (Siddiqui *et al.*, 2018). CaPs are a family of several inorganic materials with diverse properties depending on their composition and crystallinity, making them a straightforward and versatile choice for bone tissue engineering and regeneration. The current main alternative to calcium phosphates are bioactive glasses (BGs) (Rahaman, 2014). BGs have been proposed as an attractive alternative to CaPs because of their superior biological properties (Jones, 2013). Due to their faster degradation kinetics and more complex ion release profile, BGs have been correlated with improved gene expression, regulation of growth factor secretion and enhanced physiological regeneration processes, such as osteogenesis and angiogenesis (Brauer, 2015; Valerio *et al.*, 2004; Jell and Stevens, 2006). These properties were confirmed even in the presence of sole BGs, without addition of growth factors (Valerio *et al.*, 2004). Finally, beyond the CaPs and BGs families, other types of bioceramics have been investigated to impart bioactivity to polymeric materials. Among these, the most relevant are (1) metal oxides, such as titanium (Santiago-Medina *et al.*, 2015) and magnesium oxides (Hickey *et al.*, 2014), (2) non-phosphate calcium-containing inorganics, mainly wollastonite and other calcium silicates (Wu and Chang, 2013; Sanmartin de Almeida *et al.*, 2018) and (3) carbon nanotubes (Tanaka *et al.*, 2017).

Calcium Phosphates

General characteristics

Calcium phosphates are a natural choice in the development of biocomposites for bone tissue engineering applications due to their similarity to the mineral phase of bone. Combining a polymer (collagen, for instance) with a calcium phosphate is a straightforward approach to mimic natural bone tissue (Marelli *et al.*, 2011). However, calcium phosphate is a rather general term, which identifies a wide family of materials that differ in properties depending on their specific composition and structure (Rahaman, 2014). Several forms of CaPs are investigated as biomaterials: both amorphous (Skrtic *et al.*, 2003; Zhao *et al.*, 2011) (ACP) and crystalline CaPs with different formulas (Rahaman, 2014; LeGeros, 2002; Mattioli-Belmonte *et al.*, 2012), mainly hydroxyapatite (HA) (Subuki *et al.*, 2018), artificial surrogate of the natural mineral phase of bone with ideal formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, beta-tricalcium phosphates (Liu and Lun, 2012) (β -TCP, $\text{Ca}_3(\text{PO}_4)_2$) and composites of the two, usually referred to as biphasic calcium phosphates (BCP) (Dasgupta, 2018). Other formulations include tetracalcium phosphates (TTCP, $\text{Ca}_4(\text{PO}_4)_2\text{O}$) (Moseke and Gbureck, 2010), alpha-tricalcium phosphates (Carrodegua and Aza, 2011) (α -TCP, a polymorph of β -TCP) and dicalcium phosphate dehydrate (Burguera *et al.*, 2006) (DCPD, $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$). The ratio of calcium to phosphate (Ca/P) is normally used as an effective indicator to discriminate between different formulations (Rahaman, 2014). In general, CaPs share similar biocompatibility, low-toxicity and low-immunogenicity (Jeong *et al.*, 2019). In addition, calcium phosphate ceramics are usually osteoconductive (Ripamonti, 1996; Yuan *et al.*, 2001; Yamasaki and Sakai, 1992), though not osteoinductive (Rahaman, 2014). In fact, although some studies suggested that several CaPs (e.g., HA, β -TCP, BCP) have the ability to form bone in non-osseous sites, no conclusive evidence was collected to date (LeGeros, 2008). Osteoinductivity depends on numerous factors, such as the chemical composition, surface topography and macrostructure of the biomaterial (Rahaman, 2014). Pore size, structure and porosity in particular play a key role: both macro- and mesoporosity and the concavity of macropores have been linked with the ability of certain CaPs to entrap pro osteogenic growth factors (e.g., bone morphogenic protein, BMP), increasing their local concentration and ultimately enhancing the behavior of osteoprogenitor cells in situ (Reddi, 2000; Jin *et al.*, 2000; De Groot, 1998). The complexity of the phenomenon determines that osteoinductivity is most likely a property that depends on several concurring factors and cannot be defined as an intrinsic property of materials (Reddi, 2000). In parallel, bioactivity and osteoconductivity are generally considered intrinsic properties of CaPs and are deemed similar throughout the formulation spectrum of these materials (Samavedi *et al.*, 2013). Nevertheless, some differences are present. These are mostly related to the degradation kinetics of CaPs, which can highly change in relation to their composition and environmental conditions, ultimately impacting on bioactivity (Jeong *et al.*, 2019; Samavedi *et al.*, 2013). The composition and structures used in biomedical applications are the ones that are stable in aqueous media at physiological temperature (37°C). Fixing these conditions, the main parameter that will rule the degradation kinetics of a specific CaP will be the environmental pH (Rahaman, 2014). For instance, at physiological pH (7.4) the most stable CaP phase will be HA (Samavedi *et al.*, 2013), which should not come as a surprise, given that, as already mentioned, CaP normally crystallize as HA in bones. Other forms of CaPs will follow an order of increasing solubility as follows:

As a general rule, the lower the Ca/P ratio, the more acidic and water soluble the bioceramics will be (Dorozhkin, 2011). Tetracalcium phosphates are an exception to this rule, as they have the highest Ca/P ratio, (2.0), but degrade faster than HA (Ca/P = 1.67) (Rahaman, 2014). HA has the second highest Ca/P ratio and the slowest degradation kinetics among biologically relevant calcium phosphates (Rahaman, 2014). The stability of HA in body fluids can be further increased by substitution of hydroxyl ions in the lattice with fluorine, obtaining fluorapatite (FA) (Daas *et al.*, 2018).

Hydroxyapatite

The use of HA as a biomaterial dates back to the 1950s, when this calcium phosphate was used as inert bone filler, owing to its stability in vivo and its similarity to bone (Rahaman, 2014). Only later the biological reactivity of HA was better explained and exploited in medical sciences (Rahaman, 2014). Since HA has such a similar structure to the mineral phase of bone, which composes circa 69wt% of bone tissue, its use can be considered as one of first examples of a biomimicry approach in biomedical engineering (Jeong *et al.*, 2019). HA has a crystalline structure with cations and anions organized in a hexagonal lattice. The mechanical properties of HA depend on several variables, including crystal size, porosity, density, sintering or phase composition (Pielichowska and Blazewicz, 2010). The range of bending, compressive, and tensile strength values of HA are 38–250, 120–150, and 38–300 MPa, respectively (Fu *et al.*, 2011). The Young's modulus of dense HA can highly vary depending on porosity and impurities and it usually sits within a range of 35–120 GPa (Rahaman, 2014; Fu *et al.*, 2011). Other relevant mechanical properties of HA are a Weibull's modulus typical of brittle materials (i.e., 5–18), and a Vicker's hardness of 3–7 GPa (Pielichowska and Blazewicz, 2010). In general, the mechanical properties of HA are linked to its microstructure and, as such, can be improved by designing harvesting and production protocols that optimize grain fineness to obtain a densely sintered body in the final material. HA can be either of natural or artificial origin. It can be prepared artificially using a number of synthesis routes (e.g., wet precipitation, hydro-/solvo- thermal processing or sol-gel chemistry), as described in detail elsewhere (Pielichowska and Blazewicz, 2010). Natural HA is instead commonly harvested from bovine bone or obtained by processing coral minerals. The latter case consists in turning calcite (CaCO_3) into HA by a hydrothermal treatment in presence of ammonium phosphate (250°C at 100 bar pressure) (Rahaman, 2014) (Fig. 2).

Fig. 2 Crystalline structure of the unit cell of HA. Picture (a) shows the overall projection according to plan (001). The other insets show (b) the arrangement of octahedrons [Ca(1)O₆], (c) octahedral [Ca(1)O₆] and tetrahedral [PO₄] and (d) octahedral [Ca(1)O₆] and [Ca(2)O₆] together with tetrahedral [PO₄], respectively. Figure reproduced from reference Fihri, A., Len, C., Varma, R.S., Solhy, A., 2017. *Coord. Chem. Rev.* 347, 48–76, with permission of Elsevier.

Materials obtained following these routes maintain the natural three dimensional macrostructure of natural HA (i.e., an interconnected macroporosity similar to trabecular bone) and are usually characterized by consistent variations in formulation (Jeong *et al.*, 2019). As a matter of fact, HA in general is prone to elemental substitution such as Mg, Sr or CO₃ (Graziani *et al.*, 2018). This property leads to the fact that harvesting pure natural HA is nearly impossible, a great complication for process reproducibility (Jeong *et al.*, 2019). In turn, the substitution of ions or atomic clusters in synthetic HA is a well-established approach to modify the properties of the material and enhance it with diverse beneficial physicochemical and therapeutic effects (Graziani *et al.*, 2018; Ratnayake *et al.*, 2017; Cacciotti, 2016; Tite *et al.*, 2018). For example, silicon can substitute calcium ions, enhancing osteoid calcification during the early stages of mineralization even in trace amounts (Sprio *et al.*, 2008; Gibson *et al.*, 1999; Thian *et al.*, 2006). Si-substituted HA has increased bioactivity and can release Si ions that are demonstrated to stimulate osteogenesis (see section on Bioactive Glasses below) (Thian *et al.*, 2006). Copper, strontium, selenium and zinc ions have been also successfully substituted into the HA lattice and it was demonstrated that such substitutions can have several therapeutic effects, promoting osteogenesis and angiogenesis or having antimicrobial properties (Ratnayake *et al.*, 2017; Tite *et al.*, 2018; Mouriño *et al.*, 2012).

Tricalcium phosphates

Beside HA, TCP is the second main calcium phosphate used in medical devices, with several products using this material already on the market, mostly in the field of orthopedic fixation and bone fillers (Rahaman, 2014; Liu and Lun, 2012). TCPs are also widely studied as fillers for tissue engineering composite scaffolds (Samavedi *et al.*, 2013). There are two relevant polymorphs of TCP that are stable at atmospheric pressure. The main phase stable at room temperature is β -TCP. This polymorph can be produced by heating at 800–1000°C a precursor of ACP previously synthesized by precipitation (Liu and Lun, 2012). By applying a thermal treatment at $\sim 1125^\circ\text{C}$, the β -polymorph can be turned in more soluble and reactive α -TCP. This is a type of TCP that undergoes rapid direct hydrolysis upon contact with water, turning from a liquid slurry into solid HA, a characteristic that makes α -TCP an ideal candidate material for in situ setting and injectable bone cements (Carrodeguas and Aza, 2011). The more stable β -TCP, on the other hand, is most commonly used as constituent material for tissue engineering scaffolds with lower degradation rates and superior mechanical properties (Liu and Lun, 2012). Similarly to HA, TCPs can be used as carriers of dopant ions. It was demonstrated that substitution is an effective strategy to stabilize the β -phase and to increase the sinterability of β -TCP without the occurring of unwanted polymorphs (Bose *et al.*, 2011). Ions and ion clusters can also modify the overall physicochemical, mechanical, and biological properties of the final material. Some relevant examples are magnesium and strontium. The inclusion

Fig. 3 Crystal structures of α -TCP (a) and β -TCP (b). Picture reproduced from reference Goto, T., Katsui, H., 2015. *Interface Oral Health Science* 2014. Tokyo: Springer, pp. 103–115, with permission of Elsevier.

of these two ions within the TCP lattice was found to significantly improve phase stability and degradation rate while at the same time eliciting a positive effect on the growth of bone cells (Habibovic and Barralet, 2011) (Fig. 3).

In general, HA and TCP can be considered materials with complementary properties: HA is typically almost non-degradable and mechanically stronger than TCP, which in turn degrades faster and has inferior mechanical strength (Rahaman, 2014). In case intermediate properties are needed, a common viable strategy is to combine the two materials into an appropriate formulation of biphasic calcium phosphate (BCP) (Legeros *et al.*, 2003). The degradation rate of BCP can be controlled by varying its HA/ β -TCP ratio. In particular, the higher the HA/ β -TCP ratio the slower the degradation will be (Rahaman, 2014; Legeros *et al.*, 2003). Several methods are available for the production of BCP, mainly thermal treatment of Ca-deficient HA above 700°C, hydrolysis of DCPD and direct wet precipitation of calcium nitrate and diammonium phosphate (Kivrak and Taş, 2005).

Bioactive Glasses

General characteristics

The use of glasses for biomedical applications started in the late 1960s, when Professor Larry Hench and collaborators reported for the first time the unique ability of a specific silicate-based glass formulation (i.e., 45S5, later named Bioglass®) to form a strong bond to bone (Kivrak and Taş, 2005). 45S5 bioactive glass (BG) is based on a three-dimensional glass-forming SiO_2 network (45wt%) containing 24.5% Na_2O , 24.5% CaO and 6% P_2O_5 (in weight). It has high reactivity and high degradation rate in water. Over the course of the years, several other types of bioactive glasses were synthesized (Table 1) (Jones, 2013). Initially, novel compositions were developed by synthesizing small variations from the initial 45S5 formulation. In particular, the addition of glass modifiers (K_2O , MgO) was investigated to tailor the processing and physicochemical properties of the glass (Hench *et al.*, 1971). More recently, research has also focused on the doping of BGs with additional elements with attractive biological properties and therapeutic effects (biologically active ions) (Mouriño *et al.*, 2012). In addition, other glass-forming networks have been increasingly investigated. The possibility to synthesize glasses with borate and phosphate networks was demonstrated and proved itself to be a very promising strategy for the preparation of novel bioactive glasses, which expands BG applications to wound healing and soft tissue engineering (Miguez-Pacheco *et al.*, 2015).

Bioactive glasses are traditionally synthesized by conventional melt-quenching (Jones, 2013). Typically this process involves glass precursors in proper amounts to be decarbonated at around 950°C, then molten in a crucible above 1400°C and finally fast quenched in water (to retain the amorphous structure and avoid crystallization). The frit is then ground to powder. Alternatively, several formulations of bioactive glass can be produced via sol-gel method (Arcos and Vallet-Reg, 2010; Baino *et al.*, 2018a). This approach consists of the formation of a silica network by acidic- or alkali-catalyzed hydrolysis, condensation and polymerization of low molecular precursors at or near room temperature. The solution of precursors will progressively polymerize and turn into a gel that can then be dried by simple solvent casting. Sol-gel bioactive glasses possess properties that are not characteristic of similar

Table 1 Compositions (in wt%) of some notable silicate, borate and phosphate bioactive glasses

	Name	SiO ₂ (wt%)	CaO (wt%)	Na ₂ O (wt%)	P ₂ O ₅ (wt%)	K ₂ O (wt%)	MgO (wt%)	B ₂ O ₃ (wt%)

melt-based formulations (Jones, 2013). Most importantly, they have intrinsic mesoporosity (i.e., pore size of 5–20 nm) (Baino *et al.*, 2018a) and can be directly processed into desired shapes and structures during the sol phase (e.g., by electrospinning) (Kim *et al.*, 2006). The absence of high temperatures and the mesoporous structure make sol-gel bioactive glasses ideal for the loading and delivery of drugs and delicate and sensitive biomolecules (Baino *et al.*, 2017). It also allows for the formation of organic/inorganic hybrids, a novel category of materials attracting ever-growing interest thanks to their unique properties (Jones, 2013; Hench and Jones, 2015; Poologasundarampillai and Maçon, 2017). On the downside, sol-gel glasses usually have lower mechanical strength and higher degradation rates compared to melt-quenched ones, possibly due to the higher porosity intrinsic of the sol-gel route, and are generally considered not suitable for high load bearing applications (Jones, 2013). Similarly, as fillers in biocomposites, they are not normally used to increase mechanical properties, but to bring high bioactivity, drug delivery capability and other biologically relevant features to the polymeric matrix (Hench and Jones, 2015).

Silicate bioactive glasses

As previously described, the field of bioactive glasses in biomedical applications started with silicate bioactive glasses and with the formulation called 45S5 in particular, the first glass produced specifically to form a strong bond with bone. Through the decades, 45S5 Bioglass® was thoroughly studied, processed and combined with other materials, including poly(lactic acid) and poly (caprolactone) (Boccaccini *et al.*, 2010; Rezwan *et al.*, 2006), collagen (Vargas *et al.*, 2013) and alginate (Leite *et al.*, 2016; Sarker *et al.*, 2016) to make TE scaffolds. The mechanism of BG bioactivity has been also described in detail (Hoppe *et al.*, 2011; Fiume *et al.*, 2018). Briefly, 45S5 Bioglass® and other silicate BGs bond to bone thanks to the formation of a carbonate-substituted HA layer (HCA) at the surface of the glass upon contact with body fluids. HCA is highly similar to bone native minerals and it is thought to foster the adsorption of growth factors and, in turn, the guidance of cell adhesion, proliferation and differentiation into osteoblasts (Hoppe *et al.*, 2011). These cells will be triggered by the biological surroundings to produce bone ECM (collagen), which will then mineralize at the interface, progressively and seamlessly linking the material and the tissue together while the glass degrades. In particular, in the case of 45S5 BG, bioactivity is well correlated with some key compositional features of the glass: (1) a low SiO₂ content that determines lower chemical durability compared to silicate glasses; (2) high content of network modifiers (Na₂O and CaO) that reduces the network connectivity (NC) and consequently increases the degradation rate and, finally, (3) high CaO/P₂O₅ ratio (Hoppe *et al.*, 2011). 45S5 BG degrades relatively quickly (Jones, 2013). Its degradation products can be metabolized by the organism and as such the material can be called bioresorbable. The main by-products are cations (Na⁺ and Ca²⁺) that are naturally present in the body and silicon compounds, most probably silicic acid, Si(OH)₄ (Hench and Jones, 2015). The latter was most likely proved harmless, as in vivo studies on rabbit showed that it is excreted in soluble form via urine (Lai *et al.*, 2002). In spite of its strong asset of beneficial properties, 45S5 BG comes with some limitations, mostly in terms of processability. In fact, the thermal treatment of Bioglass® is challenging due to the narrow window of temperature between the glass transition temperature (T_g) and the onset of crystallization (Chen *et al.*, 2006). Heating Bioglass® often causes its partial crystallization into combeite, resulting in a glass-ceramic (Rahaman, 2014). This devitrification is a non-controlled phenomenon that can irregularly cause the decrease of mechanical properties, reduced degradation rate and reduced rate of conversion to HA (“slower” bioactivity, sometimes incomplete conversion to HA) (Rahaman, 2014). Processing methods that use high temperatures, such as extrusion-based techniques (composite extrusion, fused deposition modeling), will have to take into account this problem and try minimizing its repercussions. Another disadvantage of 45S5 BG is that in some cases its high reactivity and dissolution rate can determine a local raise in pH that could hinder its biocompatibility (Cirraldo *et al.*, 2018a). For these and other reasons, research has focused in the past decades on the identification of other formulations of silicate bioactive glasses that could tackle the limitations of the original composition when needed (Elgayar *et al.*, 2005). For instance, the notable 13–93 composition was developed by Brink *et al.* increasing the SiO₂ fraction (53wt%) and decreasing the remaining components (20wt% CaO, 6wt% Na₂O and 4wt% P₂O₅) to allow for the addition of two additional network modifiers, namely K₂O (12wt%) and MgO (5wt%) (Sharmin *et al.*, 2017; Brink, 1997). Compared to 45S5, 13–93 bioactive glass degrades and converts to HA at a slower rate.

However, it has better processing properties, in particular it can be processed by viscous flow sintering creating sintered structures without relevant crystallization (Brink, 1997). In terms of biological properties, there is no significant difference between the two silicate bioactive glasses. Studies confirmed that several cell types (e.g., MC3T3-E1 or MLO-A5) have similar proliferation and differentiation toward an osteoblast phenotype when in contact with either glass formulations (Brown *et al.*, 2008). Similarly, 6P53B glass (52.7wt% SiO₂, 18wt% CaO, 10.3wt% Na₂O, 6wt% P₂O₅, 10.2wt% MgO and 2.8wt% K₂O) is another notable Mg- and K-containing BG formulation with increased silica content, which was developed aiming at reduced degradation rate and enhanced processability (Pazo *et al.*, 1998). It is particularly used for the production of inorganic scaffolds by additive manufacturing (robocasting). Simpler compositions, such as 58S (58.2wt% SiO₂, 32.6wt% CaO and 9.2wt% P₂O₅) and 70S30C (71.4wt% SiO₂, 28.6wt% CaO), are also widely studied and were initially developed in relation to the sol-gel method, as compositions with fewer elements, and especially fewer network modifiers, are more reproducible (Jones, 2013). Finally, it is important to mention the S53P4 BG composition, another well-known BG (53wt% SiO₂, 20wt% CaO, 23wt% Na₂O and 4wt% P₂O₅), closely related to 45S5 BG and currently commercialized under the name BonAlive® (McAndrew *et al.*, 2013).

Borate bioactive glasses

In alternative to silicon oxide, boron oxide can be also used as a network former. Starting from the 13–93 silicate glass composition, the silica fraction was replaced with boron either partially (e.g., 13–93B1, 34.4wt% SiO₂, 19.9wt% B₂O₃, 19.5wt% CaO, 5.8wt% Na₂O, 3.8wt% P₂O₅, 4.9wt% MgO and 11.7wt% K₂O) or completely (i.e., 13–93B3, 56.6wt% B₂O₃, 18.5wt% CaO, 5.5wt% Na₂O, 3.7wt% P₂O₅, 4.6wt% MgO and 11.1wt% K₂O) (Fu *et al.*, 2010a,b). Compared to silicate bioactive glasses, borate formulations are less chemically durable and degrade faster once in contact with body fluids (Fu *et al.*, 2010b). This behaviour determines that borate bioactive glasses usually have a higher conversion rate to HA, compared to 13–93 or even 45S5 BGs (Liu *et al.*, 2013), but at the same time it raises concerns about possible toxic effects: high release of (BO₃)³⁻ ions is known to be cytotoxic (Landolph, 1985), as in vitro studies on murine MLO-A5 cells have confirmed (Fu *et al.*, 2010a). Fortunately, ion concentration reaches dangerous levels only when observed in static in vitro models. Boron blood concentration levels were monitored in a rabbit tibiae model and were found to be far below the toxicity level (Zhang *et al.*, 2010b). In addition, no adverse nephrotoxic or hepatotoxic effect due to 13–93B3 was assessed when testing glass granules in vivo in a subcutaneous rat model (Rahaman, 2014). Non-toxic borate ion concentrations were actually associated with therapeutic effects both in terms osteogenesis and angiogenesis, thanks to their activation of MAPK signaling (Capati *et al.*, 2016) and upregulation of VEGF and TGF-β1 growth factors (Dzondo-Gadet *et al.*, 2002), respectively. To further strengthen the safety of borate bioactive glasses, the possibility to manipulate and control their degradation behavior was investigated. In particular, it was observed that the glass degradation rate can be significantly reduced by increasing the silicate content and it is maximized in purely borate glasses (Fu *et al.*, 2010b). Compositional variations can also be useful to introduce in the glass trace elements that favor bone growth, angiogenesis or tackle bacterial colonization. For instance, 13–93B3 was doped with 0.4wt% CuO and implanted in a rat subcutaneous site, finding that the addition of copper can effectively enhance angiogenesis (Bi *et al.*, 2012). Thanks to their highly tailorable degradability and ease of manufacture borate bioactive glasses are a novel very promising alternative to silicate-based ones. As a matter of fact, medical devices based on this class of glasses are already on the market: a non-woven wound healing mash (Mirragen®) was recently developed and commercialized by ETS Wound Care, USA (Bi *et al.*, 2012). The device also recently obtained FDA clearance. The mash is specifically developed for chronic wounds and can support and improve skin regeneration thanks both to its fibrous structure and the quick release of therapeutic ions from high degradation rate borate glass (Fiume *et al.*, 2018; Baino *et al.*, 2018b).

Phosphate bioactive glasses

In recent years, the synthesis and applications of phosphate bioactive glasses have been also explored (Brauer, 2012; Knowles, 2003). Phosphate bioactive glasses are based on the glass-forming properties of P₂O₅ using CaO and Na₂O as primary modifiers (Brow, 2000). They are usually divided in three families depending on the phosphate content: ultraphosphate glasses, with more than 50 mol% of P₂O₅ (2.5 < O/P < 3), metaphosphate glasses, with a P₂O₅ content of 50 mol% (O/P = 3) and polyphosphate glasses when the phosphate content is lower than 50 mol% (O/P > 3) (Knowles, 2003). In addition, so-called invert glasses can be produced with less than 33.3 mol% phosphate (Walter *et al.*, 2001). In these glasses, the network is formed by orthophosphates and pyrophosphates and the fraction of complementary elements (e.g., calcium, sodium) is higher than the phosphate content. Invert glasses offer a possible compositional solution to reduce glass hydrolysis, however they are difficult to manufacture due to their narrow processing window (Walter *et al.*, 2001). Likewise other bioinorganic platforms, phosphate-based glasses can be used as therapeutic ion carrier by selective doping with specific trace elements within the network (e.g., copper, boron, strontium or selenium) (Łapa *et al.*, 2019).

Phosphate bioactive glasses are constituted by the main elements of the mineral phase of bone (calcium and phosphate) and, as such, they offer a strategy to avoid the long term persistence of network formers (e.g., silicon) in vivo (Knowles, 2003). They are highly resorbable (they are often deemed “soluble”) (Navarro *et al.*, 2005) and versatile in terms of degradation rate, which can be vastly tailored by changing the chemical composition (Sharmin *et al.*, 2017). In addition, they are characterized by good processability, in particular by melt fiber drawing (Rinehart *et al.*, 1999; Muñoz-Senovilla *et al.*, 2017; Massera *et al.*, 2014). However, differently to the more common silicate ones, phosphate glasses are generally characterized by relatively faster and more acidic degradation (i.e., local pH lowers significantly during dissolution in buffer solutions) (Rinehart *et al.*, 1999). Some formulations of phosphate glasses, especially ternary CaO–Na₂O–P₂O₅, are characterized by very fast degradation (i.e., within 7 days) and great

Fig. 4 Schematic representation of the network structure of silicate, borate and phosphate glasses (left to right).

reduction in local pH (Salih *et al.*, 2000; Ahmed *et al.*, 2004). However, as typical for most bioactive glass systems, these issues can be solved by compositional modifications (Abou Neel *et al.*, 2008). Most remarkably, studies showed that the weight loss and release of ions from phosphate glasses follow a steady linear trend, compared to the burst/plateau release trend of silicate networks (Rahaman, 2014). The linear release of ions is considered a key difference between phosphate and silicate bioactive glasses and a strong asset of the former (Fig. 4).

Other bioactive ceramics

Besides calcium phosphates and bioactive glasses, numerous other materials are being investigated as bioactive fillers of polymer-based biocomposites for bone tissue engineering. A typical approach is to use other calcium-containing ceramics, mainly calcium silicates or calcium carbonates. Diopside ($\text{CaMgSi}_2\text{O}_6$), akermanite ($\text{Ca}_2\text{MgSi}_2\text{O}_7$), bredigite ($\text{Ca}_7\text{MgSi}_4\text{O}_{16}$) and, above all, wollastonite (CaSiO_3) were reported as main calcium silicate alternatives to CaPs and BGs in bone tissue engineering, especially thanks to their superior mechanical properties (Wu and Chang, 2013; No *et al.*, 2017). In particular, the interest in the use of wollastonite grew in the past decade due to higher reported bioactivity compared to other silicates (Wu and Chang, 2013). Several reports demonstrate the possibility to use this calcium silicate for the preparation of inorganic 3D porous scaffolds as well as of biocomposites (Li and Chang, 2005a; Ye *et al.*, 2008; Mostafa and Zaki, 2015). Similarly to other bioceramics, wollastonite degrades releasing calcium and silicon ions, which are known to be able to enhance osteogenic and angiogenic differentiation and to trigger biomineralization (i.e., bioactivity), as demonstrated by several studies both in vitro and in vivo (Wu and Chang, 2013). As mentioned above, calcium carbonates (calcite and aragonite) were also investigated as possible biomaterials for tissue engineering, owing to their bioactivity and resorbability (Peng *et al.*, 2016; Lopez-Heredia *et al.*, 2017). In particular, a promising calcium carbonate-based material of natural origin is nacre. Nacre can be obtained from mussels. It structurally consists of an inorganic aragonite lamellar phase dispersed within an organic matrix. Previous studies demonstrated its biocompatibility, bioactivity and osteoconductivity. Most remarkably, nacre has outstanding mechanical properties that can be ascribed to its highly organized structure that makes it highly competitive against other bone tissue engineering biomaterials. The use of bulk nacre as well as of composites of it with polymers (e.g., various saturated poly- α -hydroxy esters, polyhydroxyalkanoates) were explored and recently reviewed elsewhere (Gritsch *et al.*, 2019; Deville *et al.*, 2006; Gerhard *et al.*, 2017).

Due to its bioresorbability and its important role in bone remodeling and skeleton development, magnesium and its oxide (MgO) were also investigated as bioactive filler to a polymer phase (Hickey *et al.*, 2014; Diba *et al.*, 2014). Mg ions have been linked to a number of important physiological events. They seem to have an effect in increasing differentiation towards the osteogenic phenotype and regulating the activity of osteoblast integrins and their ability to attach to the substrate. In particular, Mg^{2+} can bond to integrins α subunits, modulating cell affinity to the biomaterial surface (Wong *et al.*, 2014). Besides the possibility of substituting Mg ions within the networks of previously described bioceramics (e.g., Mg-HA, Mg-diopside or Mg-containing bioactive glasses), magnesium has been explored as a possible filler both as metallic or MgO micro- and nanoparticles (Hickey *et al.*, 2014; Diba *et al.*, 2014; Wong *et al.*, 2014; Nasri-Nasrabadi *et al.*, 2018). Magnesium microparticles introduced in a polycaprolactone matrix, for example, were found to increase both the native mechanical properties and bioactivity of the polymer (Suryavanshi *et al.*, 2017). Magnesium oxide offers further advantages, as it is known to be an effective antibacterial agent with significantly easier handling and higher shelf life compared to the bare metal. Interestingly, MgO was found to be more biologically effective when formed as particles compared to the bulk, making it an ideal candidate as filler for bioresorbable composites (Hickey *et al.*, 2014).

Another relevant oxide reported as filler in biocomposites is titanium dioxide (TiO_2) (Gerhardt *et al.*, 2007; Wei *et al.*, 2008; Haldorai, 2018; Kim *et al.*, 2014b). Titanium oxide naturally forms on titanium surfaces when in contact with body fluids. It has excellent biocompatibility and it can regulate osteoblast differentiation. The actual mechanism of action is still under investigation and it is not clear whether osteoblast differentiation is affected by the titanium oxide itself or by oxygen released from the material (Santiago-Medina *et al.*, 2015). Some authors suggest that oxygen tension can increase in presence of titanium oxide and that it can

have a strong effect on osteoblast differentiation (Nicolaije *et al.*, 2012). Results seem to confirm that hypoxia shifts differentiation from the osteogenic to the chondrogenic phenotype (Heppenstall *et al.*, 1976). In general, the influence of TiO₂ on the gene expression of osteoblast cells was confirmed (Santiago-Medina *et al.*, 2015; Salim *et al.*, 2004). However, the effect of titanium oxide goes beyond chemotaxis: physical factors such as roughness and other microstructural features play a particularly important role in determining the biological properties of this material (Santiago-Medina *et al.*, 2015). For instance, when combined with poly(D,L-lactic acid) (PDLLA) (Gerhardt *et al.*, 2007; Wei *et al.*, 2008), TiO₂ was found to improve the nanometric features and roughness of the polymer alone, resulting in a nanometric topography that resembles the one of native bone (Gerhardt *et al.*, 2007). This difference in topography was linked with an increase in HA formation and with increased osteoblast adhesion on the surface of composite specimens with high TiO₂ loading. No bioactivity was assessed either on the polymer alone, on TiO₂ nanoparticles or on composites with low filler content (Gerhardt *et al.*, 2007). This suggests that high nanoparticle content, determining an increase in surface roughness, may improve both cell adhesion and bioactivity. Similar promising results were obtained with natural polymers, such as chitosan (Haldorai, 2018) and silk fibroin (Kim *et al.*, 2014b).

In the past decade, carbon nanotubes (CNTs) have emerged as a very promising candidate biomaterial, fostering rich literature on the topic (Li *et al.*, 2010; Sahithi *et al.*, 2010; Zhang *et al.*, 2010a; Beg *et al.*, 2011). They are a relatively recent class of nanomaterials discovered in 1991 (Iijima, 1991), an allotrope of carbon consisting of an hexagonal lattice bent on itself to form a hollow cylinder. Among their several other applications, it was demonstrated that CNTs can be used by themselves for the fabrication of pure-CNTs scaffolds, as reported for instance by Tanaka *et al.* (2017), where the group reported the production of porous constructs by foaming. As an alternative, CNTs can be incorporated into a composite with either polymeric (Magiera *et al.*, 2017; Kaur *et al.*, 2017) or inorganic (Bai *et al.*, 2010; Boccaccini *et al.*, 2007) matrices. These composites generally have highly increased mechanical properties compared to the native polymer, thanks to the outstanding tensile strength and flexibility of CNTs, but at the same time high integrity and low brittleness owing to the bonding capability of the polymer (e.g., polycaprolactone or polypropylenefumarate, see following section) (Mattioli-Belmonte *et al.*, 2012). Despite their remarkable physical properties, one reason that prevented the spreading of investigation on CNTs is the concern that exists regarding their safety (Padmanabhan and Kyriakides, 2015; Ema *et al.*, 2016). The debate over their biocompatibility is indeed still open, as some studies reported possible cytotoxic effects upon degradation (Francis and Devasena, 2018), while others endorse their biological compatibility, even showing improvements in terms of cell adhesion and proliferation (Kaur *et al.*, 2017; Cheng *et al.*, 2013). Further investigations will have to look more in-depth at this controversial point in order to understand what will be the future of CNTs in biomaterials science.

Biodegradable Polymer Matrices

The matrix of a composite tissue engineering scaffold is responsible for holding together the structure, bonding the filler particles/fibers, while at the same time providing a suitable substrate for cell attachment and proliferation. Several different materials and combinations of them have been proposed over the years, each one with properties that suit specific applications and with synergies with specific bioceramics. Generally speaking, biodegradable polymers are divided into two categories depending on their origin: synthetic or natural. Synthetic polymers, principally saturated and unsaturated polyesters, have the advantage of complete control over key properties like degradation kinetics, mechanical behavior or pore structure and size. However, they usually are hydrophobic and biologically inert. On the other hand, natural polymer mimic closely the structure or even the composition of the ECM. They are high in water content, bioresorbable, biocompatible and usually more biologically active (i.e., can elicit specific responses from cells) than synthetic polymers. Yet, their origin and the need to extract them from natural sources imply that they are (1) less available, (2) with more irregular physical properties and (3) more often immunogenic, in comparison with synthetic polymers. In this section, the key synthetic and natural polymers for the production of biocomposites are listed and their properties discussed. In particular, the reasons to combine them into composites and the bioceramics they were combined with will be mentioned.

Synthetic Polymers

Saturated poly- α -hydroxy esters

Saturated poly- α -hydroxy esters are probably the most widespread family of synthetic biodegradable polymers used in the fabrication of biocomposites for tissue engineering and other biomedical applications (Li, 2017; Zhou *et al.*, 2012; Habraken *et al.*, 2007). The most notable examples of this class are linear polymers synthesized from glycolic acid, lactic acid (both L and D stereoisomers) and ϵ -caprolactone monomers, or copolymers of the above. Their popularity is due to their biocompatibility, their tailorable mechanical and degradation properties and their versatility (Li, 2017; Vert *et al.*, 1992; Girones Molera *et al.*, 2012). The possibility to synthesize a wide range of copolymers makes saturated poly- α -hydroxy esters a very powerful toolbox for the fabrication of polymers with very diverse properties by varying the molecular weight, the monomers and the stereoregularity (Vert *et al.*, 1992, 1994). In addition, they are easy to process through a wide spectrum of typical forming methods, such as film casting, foaming, fiber spinning and most thermoforming approaches (e.g., extrusion, injection molding) (Gritsch *et al.*, 2019). Thanks to their convenient mechanism of degradation and processability, these bioresorbable polymers are approved by the FDA for use in

various devices in contact with body fluids and are currently under commercial use in several medical applications (Lunt, 1998; Malikmammadov *et al.*, 2018). The main mechanism of biodegradation of saturated poly- α -hydroxy esters consists of de-esterification through hydrolytic degradation (Schwach and Vert, 1999). Once in contact with body fluids, the polymer uptakes water and the reaction is catalyzed by both acids and alkalies in solution. Polyester hydrolysis can be also autocatalyzed by the terminal carboxylic acids of the polymer chains. Most importantly for medical applications, the degradation by-products of these polymers can be readily disposed by the organism through physiological pathways, mainly by the citric acid cycle (CAC). Degradation kinetics are affected by a wide range of parameters, including chemical structure, molecular weight (MW), polydispersity (PD), crystallinity, additives, device size and morphology, mechanical stress/strain, processing techniques and environmental conditions (Vert *et al.*, 1992, 1994). For instance, for both poly(glycolide-co-lactide) and poly(DL-lactide) the degradation kinetics highly vary depending on the content of L- and D-lactic acid monomers (Kimura, 2009). In spite of their several advantages, this class of polymer presents a major drawback: especially for thick structures, degradation tends to proceed heterogeneously and from the bulk of the materials (Grizzi *et al.*, 1995). Bulk erosion is very dangerous, as it can cause premature failure of the device, abrupt release of by-products and quick pH drop, which in turn can trigger a strong inflammatory response (Schwach and Vert, 1999; Grizzi *et al.*, 1995). Generally, the phenomenon is thought to be caused by a joint effect of the adsorption of degraded oligomers into the inner side of the device, the autocatalytic effect of carboxylic end groups of the polymer and the neutralization of surface pH by the buffer (both in vitro and in vivo) (Schwach and Vert, 1999; Siparsky *et al.*, 1998).

The acidic degradation of PLA, PGA, PCL and their copolymers poses significant limits to their use in biomaterials science, as the materials have been implicated in adverse tissue reactions, especially in the case of massive devices (Ramot *et al.*, 2016; Narayanan *et al.*, 2016). In the last decades, research focused on the identification of possible strategies to reduce autocatalysis and pH decrease of these polyesters in order to enhance their biocompatibility and control their degradation. Review papers are available, discussing in-depth how to tackle the consequence of the hydrolysis of saturated poly- α -hydroxy esters (Valentina *et al.*, 2017; Shasteen and Choy, 2011). Among other possible approaches, a major cost-effective strategy is to prepare composites combining these polymers with bioinorganic species such as bioactive glasses (Boccaccini *et al.*, 2010; Blaker *et al.*, 2005; Conoscenti *et al.*, 2018) and calcium phosphates (Rezwan *et al.*, 2006; Zhou *et al.*, 2012; Danoux *et al.*, 2014). In fact, the possibility of counteracting the acidic degradation of many biodegradable polymers is one of the main reasons that justifies the use of composites. PLA- and PGA-based polymers are probably the most widely studied materials in this sense. Several isomers of PLA and copolymers with PGA were combined with an array of different bioactive glasses, including 45S5 (Eqtesadi *et al.*, 2016b; Rezabeigi *et al.*, 2016; Simpson *et al.*, 2015), 13–93 (Xiao *et al.*, 2017; Eqtesadi *et al.*, 2016a) and doped compositions (e.g., strontium) (Lee *et al.*, 2019), calcium phosphates (Zhou *et al.*, 2012; Danoux *et al.*, 2014; Shin *et al.*, 2018) and silicates (Su *et al.*, 2017), metal oxides (Marra *et al.*, 2016) and carbon based nanomaterials (Gonçalves *et al.*, 2017). Similarly, PCL has been also combined with several different phases using various techniques, as thoroughly summarized in a recent review (Hajiali *et al.*, 2018).

Polypropylene fumarate

Polypropylene fumarate (PPF) is, just like PLA or PGA, a linear polyester based on propylene glycol and fumaric acid, a component of the CAC (Yan *et al.*, 2011). Contrarily to saturated poly- α -hydroxy esters, PPF has the advantage of containing unsaturated bonds (Kasper *et al.*, 2009). These C–C double bonds allow for crosslinking of the polymer into a covalent network either alone or in combination with other moieties (e.g., N-vinyl pyrrolidone, poly(ethylene glycol)-dimethacrylate) (Kasper *et al.*, 2009; He *et al.*, 2000). Molecular weight distribution, unsaturation ratio and crosslinking degree of PPF can be controlled in order to tailor its degradation rate and mechanical properties. In addition, when combined with appropriate initiators, PPF can be used for the development of injectable platforms for in situ crosslinking (He *et al.*, 2000). The molecular characteristics of PPF will be key in shaping the material depending on the specific application: high MW and polydispersity PPF can reach very high viscosities before crosslinking and be very hard to handle and mold into shape. The complexity in processability is generally considered one of the major drawbacks of this family of polymers (Rezwan *et al.*, 2006). In terms of degradation, PPF is degraded hydrolytically similarly to saturated poly- α -hydroxy esters into biocompatible by-products that can be readily removed from the body through physiological pathways. Compared to saturated polyesters, PPF is characterized by lower acidification upon degradation and as such it is a very promising strategy to overcome the drawbacks of PLA-based technologies (Rezwan *et al.*, 2006; Kasper *et al.*, 2009). As a matter of fact, several PPF-based approaches were explored aiming at its biomedical application for orthopedic implants, tissue engineering scaffolds and controlled drug delivery (Cai *et al.*, 2019). In particular, in the context of tissue engineering and regenerative medicine, PPF and its composites have been investigated for the development of injectable substitutes, combining this very promising polymer with bioactive ceramic particles, β -TCP and HA in particular (Diez-Pascual, 2017; Westbrook, 2016). However, in spite of the encouraging results obtained so far, PPF has been investigated to a lesser extent, in comparison with the extensive research published on composites of saturated poly- α -hydroxy esters.

Biodegradable polyurethanes

Polyurethanes (PU) are a family of polymers composed of monomers linked together by carbamate, or urethane bonds (Burke and Hasirci, 2004; Sobczak, 2015). They are mostly thermosetting and as such unsuitable for temperature-based fabrication techniques (Hasirci and Aksoy, 2007). There are however studies reporting the synthesis of thermoplastic polyurethanes that can be, for example, extruded and 3D printed (Mi *et al.*, 2014; Cui *et al.*, 2019). In a typical synthesis, a polyisocyanate or an isocyanate-terminated prepolymer is reacted with a polyol to give an alternating chain copolymer of the two. In the case of polyurethane for bone grafts, the polyisocyanates used are most frequently either lysine- or hexamethylene diamine-derived, as they offer good

performance with lower toxicity compared to standard aromatic polyisocyanates (Hasirci and Aksoy, 2007). The degradability of polyurethanes depends on their chemical structure. There are non-biodegradable, inert PU as well as highly biodegradable ones. In particular, it is the polyol component that determines greatly the degradation rate of the final cured polymer (Hasirci and Aksoy, 2007). For instance, polyurethanes based on polycarbonate hydrolytically degrade slower than the ones based on polyethers, which in turn degrade slower than polyester-based PU (Hasirci and Aksoy, 2007). The advantage of polyurethanes in bone tissue engineering is to have a very versatile platform that permits the exploration of diverse properties depending on the specific selected chemistry. The product of polyurethane synthesis can in fact be finely tailored in its properties by mindful control of the initial reagents. Polyurethanes offer a superior solution in terms of synthesis-tailored mechanical and degradation properties, non-toxic degradation by-products and drug carrying capability (Burke and Hasirci, 2004). Their setting behavior makes them ideal candidates for the development of injectable biomaterials. Furthermore, they possess the intrinsic ability to be formed into porous foams, ideal for tissue engineering, by simple synthesis in presence of water (Guelcher *et al.*, 2004). Bioactive fillers can be added to the polymer in order to create a biocomposite with superior properties. In particular, promising results have been obtained combining polyurethanes with 45S5 bioactive glass (Ryszkowska *et al.*, 2010), HA (Cui *et al.*, 2019), fluorapatite (Asefnejad *et al.*, 2011), β -TCP (Aguilar-Perez *et al.*, 2018) and titanium particles (Aguilar-Perez *et al.*, 2018).

Natural Polymers

Polypeptides

Among natural polymers, polypeptides seem a natural choice: protein-based biomaterials tend to fold and self-assemble on a molecular level, forming a growth substrate that offers better mimicking of the natural ECM compared to synthetic polymers (Curry *et al.*, 2016). Polypeptide biopolymers are traditionally animal-sourced, although recombinant varieties are also studied (Yang *et al.*, 2004; Wu *et al.*, 2017). They are characterized by competitive bioresorbability and bioadhesion. In addition, owing to the hierarchical organization typical of proteins, they offer cues to cells on many different levels: from ligand motifs in their primary structure (e.g., RGD sequences) to topographical signaling of secondary to quaternary structures (Curry *et al.*, 2016). Polypeptides are also very versatile in terms of functionalization and engineering of biologically responsive materials, thanks to their numerous reactive groups and possible biological responses (e.g., binding metal ions and ligands) (Tallawi *et al.*, 2015; Mas-Moruno, 2018; Gómez-Guillén *et al.*, 2011).

Being the main component of the extracellular matrix, collagen is perhaps the most frequently studied polypeptide for tissue engineering scaffolds (Lee *et al.*, 2001). Collagen is mainly synthesized by fibroblasts and it makes up for 25%–35% of the whole-body protein weight content and 90% of the organic component of the bone ECM (Gelse, 2003). There are approximately twenty-nine known types of collagen (Ricard-Blum, 2011). Among these, type I collagen is the most commonly used, thanks to its higher availability and lower immunogenicity (Ricard-Blum, 2011). The main beneficial properties of collagen are that it is intrinsically biocompatible, biodegradable and with a good potential to stimulate cell proliferation and differentiation both in vitro and in vivo (Lee *et al.*, 2001). In terms of disadvantages, collagen tends to cause possible antigenic responses (Lynn *et al.*, 2004). It also have poor dimensional stability due to swelling in vivo and low mechanical properties, especially for load bearing scaffolds. Although stability and mechanical properties can be improved via crosslinking (physical, chemical or enzymatic, described in detail elsewhere (Meyer, 2019)), they usually are insufficient for its stand-alone application. Composite approaches are great strategies to increase mechanical properties while developing a structure that more closely resembles native bone (i.e., collagen + hydroxyapatite), especially when using bioinspired calcium phosphates (Curry *et al.*, 2016). However, the composite approach for collagen does not avoid immunogenicity (Zhang *et al.*, 2018). A possible way to overcome this issue is to use gelatin. Gelatin is denatured collagen produced mainly from type I collagens of different origin: bovine, porcine and, in more recent years, fish, sea urchin, jellyfish and bird feet (Liu *et al.*, 2015). Since the primary structure of collagens of different origin will be not exactly the same, the composition of gelatin can vary. However, all varieties are principally composed of proline, hydroxyproline and glycine with smaller traces of other amino acids (Liu *et al.*, 2015). Regardless of the amino acid composition, the denaturation process destroys the supramolecular fibrillary structure of collagen, which is thought to be responsible for its immunogenicity (Lynn *et al.*, 2004). This results in gelatin being non-immunogenic, but also determines a drop in mechanical properties and stability in aqueous environments. In fact, gelatin dissolves in water within a few hours and for effectively using it, its stabilization via crosslinking, most commonly with aldehydes, carbodiimide (EDC) chemistry or genipin, is required (Yahia *et al.*, 2015). For instance, Lacroix *et al.* (2014) prepared composites of 75S25C bioactive glass and gelatin crosslinked using glutaraldehyde. Porous constructs were prepared using poly(methyl metacrylate) (PMMA) beads as porogen agent and they showed similar bioactivity to pure bioactive glass scaffolds, but with higher compressive strength. Other examples of filler phases for gelatin are HA (Landi *et al.*, 2008), β -TCP (Takahashi *et al.*, 2005) and different formulations of bioactive glasses, including nano-sized sol-gel derived bioactive glass (64.5wt% SiO₂, 29.5wt% CaO, 6.5wt% P₂O₅) (Hafezi *et al.*, 2012) and Mg- and Zn- doped BGs (Raz *et al.*, 2018). Usually, gelatin-based scaffolds are produced by freeze-drying. In some remarkable cases, the high dissolution rate of gelatin seems to naturally increase the native bioactivity of collagen, as some studies report increases in biomineralization after addition of gelatin to a PLLA matrix (Magiera *et al.*, 2017). Additionally, the high-throughput production of gelatin is a relative simple process to implement, making it more available and cost-effective than non-denatured collagen (Liu *et al.*, 2015).

In alternative to collagen-based biopolymers, silk derivatives are highly studied for biomedical applications in diverse tissues (Bhattacharjee *et al.*, 2017; Farokhi *et al.*, 2018). Silk is a protein-based natural material produced mainly by *Lepidoptera* larvae and

adult web arthropod spinners. As a biomaterial, silk can be used for the preparation of textile-based braided scaffolds and grafts (Bhattacharjee *et al.*, 2017; Catto *et al.*, 2014). In particular, in the context of bone regeneration, remarkable results were obtained when silk braided structures were correlated with spatially regulated formation of hydroxyapatite following a mineralization mechanism that resembled the one of collagen type I in bone (He *et al.*, 2013). Although notable results were attained using native silk, studies tend to agree that for biomedical applications the separation of silk in its two constitutive compounds, fibroins and sericins, seems to give better and more tailorable results, owing to the completely different nature of the two protein families that can be individually engineered. Generally, fibroin proteins are the major constituent of silk (72%–81% of a cocoon). It is a hydrophobic glycoprotein that, as such, is insoluble in water. Fibroin molecules are in fact very stable owing to their ability to establish a high number of intermolecular hydrogen bonds. Dissolution can be achieved by disruption of these H-bonds using chaotropic agents, most commonly lithium bromide, and by subsequent dialysis (Lu *et al.*, 2011). Fibroin has a semi-crystalline structure in which two phases coexist: highly ordered crystalline antiparallel β -sheet domains (silk I) interposed by loose regions of mixed α -helix, β -sheet and random coiling (silk II) (Cilurzo *et al.*, 2011; Qi *et al.*, 2017). The mechanical properties of fibroin are highly dependent on the ratio between the two phases: while a higher silk I content contributes to strength and toughness, silk II makes fibroin more flexible and elastic (Qi *et al.*, 2017). Most interestingly, the ratio between silk I and II can be controlled through well-established and scalable processes (e.g., methanol conditioning to increase silk I content, water vapor annealing to increase silk II) (Lu *et al.*, 2011). The possibility of tailoring the secondary structure of fibroin, and therefore its degradation and mechanical properties, makes it a more processable and tailorable biomaterial for tissue engineering, as compared to native silk (Cilurzo *et al.*, 2011). Additionally, fibroin is also known to have minimal immunogenicity, high cytocompatibility and to directly regulate several signaling pathways responsible for osteogenic differentiation (Farokhi *et al.*, 2018; Santin *et al.*, 1999). Nonetheless, the osteogenic potential of fibroin was deemed not sufficient and additional strategies have to be developed to achieve substantial bone growth (Farokhi *et al.*, 2018). For instance, bioactive, osteopromotive components should be associated with silk fibroin to overcome its drawbacks (Farokhi *et al.*, 2018; Kim *et al.*, 2014a). The combinations of fibroin with either hydroxyapatite (Farokhi *et al.*, 2018) or bioactive glasses (Du *et al.*, 2019) are current main research trends as regards this biopolymer, with comprehensive reviews available on both topics (Farokhi *et al.*, 2018; Midha *et al.*, 2018). Other explored approaches include the addition of carbon nanotubes (Ayutsede *et al.*, 2006) or TiO₂ (Kim *et al.*, 2014b) for mechanical toughening.

Parallel to fibroin, sericin can also be isolated from silk cocoons. Contrary to fibroin, sericin is hydrophilic. Its structure is composed by two subunits: α - and β -sericin, they organize mainly into random coils with minor elements in β -sheet conformation (Padamwar and Pawar, 2004). Although it is traditionally considered as a waste product of the purification of fibroin, recent studies pointed out the favorable properties of sericin and suggest further investigation to use it in biomedical sciences (Kunz *et al.*, 2016; Yooyod *et al.*, 2016). Research efforts to date have been negligible due to immunogenicity concerns for the use of this protein (Kunz *et al.*, 2016). Nevertheless, recent reports support the idea that, as long as it is used in absence of fibroin, antigenic responses subsequent to sericin exposure are minimal (Wang *et al.*, 2015). Owing to its hydrophilicity, antibacterial and antioxidative properties and UV-protective ability, sericin was proposed as wound dressing/skin protection biomaterial (Ersel *et al.*, 2016; Qi *et al.*, 2018). Higher hydrophilicity in particular is known to induce greater collagen synthesis, as compared to fibroin. Sericin also showed promising results for bone regeneration. When used alone, it can be used for the preparation of biomimetic composites, since it spontaneously induces hydroxyapatite nucleation provided that the β -sheet content is high when immersed in a metastable calcium phosphate solution (Zhang *et al.*, 2014; Takeuchi *et al.*, 2005; Li *et al.*, 2016). In parallel, sericin can also promote the secretion of tumor necrosis factor- α (TNF- α), an important growth factor associated with osteogenesis (Jo *et al.*, 2017). In a more traditional composite approach, sericin was also proposed as matrix for bone tissue engineering composite scaffolds in combination with calcium phosphates, resulting in constructs with high adhesive properties, improved cell viability and increased osteoblast differentiation (Vedakumari *et al.*, 2020). Similar results were obtained when applying sericin as a coating on titanium implants: adhesion, proliferation and differentiation of osteoblast cells were enhanced in presence of the protein (Nayak *et al.*, 2013).

Polysaccharides: chitosan, cellulose, starch, alginate, pectin

Naturally derived polysaccharides are widely studied for the fabrication of a variety of tissue engineering composite scaffolds (Pacheco *et al.*, 2018). They have similar properties to polypeptides: they are biocompatible and biodegradable. However, they are usually obtained from more accessible and available sources and, as a consequence, can be produced cost-effectively in higher quantity (e.g., cellulose and chitin are the first and second most common biopolymers on the planet, respectively). Notable representatives of this category are chitin, chitosan, cellulose, alginate, starch and pectin, among others. Natural polysaccharide biopolymers can be sourced from animals (chitin, chitosan), plants (cellulose, alginate, pectin, starch) or microorganisms (cellulose) (Schuerch, 1985).

Chitosan is a semicrystalline, partly deacetylated derivative of chitin, a major structural component of the exoskeleton of crustaceans as well as the carbohydrate skeleton of fungi. It is composed of randomly organized glucosamine and N-acetyl glucosamine units (the ratio between deacetylated and acetylated monomers is defined as degree of deacetylation) (Zargar *et al.*, 2015). Chitosan is not found in mammals or other vertebrates, but nonetheless it has ideal properties for biomedical applications (Levengood and Zhang, 2014). It is mildly hydrophilic (i.e., contact angle ~ 70 – 80°), biocompatible, intrinsically antibacterial and mucoadhesive. It is known to modulate the activity of inflammatory cells to promote wound healing and the activity of blood cells towards hemostasis (Cheung *et al.*, 2015). In addition, the foreign body response and risk of fibrous encapsulation upon in vivo implantation of chitosan is minimal (Archana *et al.*, 2013). Most of its properties are thought to be due to its rich content of amines and its cationic nature at neutral pH and can be effectively tailored by controlling the molecular weight and degree of deacetylation (Zargar *et al.*, 2015). The high amount of reactive residues (both primary amines and hydroxyls) also determine that

chitosan can be readily functionalized and modified according to the need (Mourya and Inamdar, 2008). The solvent and melt blending of chitosan with other polymers has been also studied in-depth. Remarkably, it was demonstrated that imidazole- or methyl pyrrolidinone-modified chitosans are osteoconductive in vivo and can promote bone regeneration (Muzzarelli *et al.*, 1993). Other than with chemical functionalization, the osteoconductivity of chitosan for its use in bone tissue engineering can be also enhanced by means of inorganic fillers (Levengood and Zhang, 2014). Rich literature is available about the combination of chitosan with bioceramics, with a clear focus on the use of several forms of calcium phosphates, mainly hydroxyapatite (Brun *et al.*, 2014; Pighinelli and Kucharska, 2013; Lei *et al.*, 2017; Ramahdita *et al.*, 2018) and tricalcium phosphates (Kuo *et al.*, 2009; Viswanathan *et al.*, 2019; Puvaneswary *et al.*, 2015; Liu *et al.*, 2006). The combination with several formulations of bioactive glasses (Martins *et al.*, 2018; Luz and Mano, 2012; Caridade *et al.*, 2013; Liverani *et al.*, 2018) and with oxides of titanium (Hal-dorai, 2018), magnesium (Sanuja *et al.*, 2014; Praffulla and Bubbly, 2018) silver and zinc (Motshekga *et al.*, 2015) were also investigated and reported with very promising results both in terms of physicochemical and biological properties.

The use of cellulose as biocompatible and abundant material for tissue engineering scaffolds was also proposed (Hickey and Pelling, 2019). Cellulose is a homopolymer of β (1-4) linked D-glucose and it is the most common biopolymer on Earth (Sharma *et al.*, 2019), a tremendous economic advantage compared to other biomaterials. It is currently mainly extracted from plant lignocellulose, although the use of bacterial cellulose was recently proposed and it is now rising as a promising strategy for the development of scaffolds (Torgbo and Sukyai, 2018). Compared to plant-derived cellulose, bacterial cellulose has higher purity, better structural properties, water absorption and mechanical strength, all avoiding the polluting processes necessary to extract cellulose from lignocellulose (Jang *et al.*, 2017). Furthermore, bacterial cellulose is directly synthesized in the form of nanofiber networks, a strong asset for its biomedical application: the material as prepared already presents an ideal topography for cell growth and attachment, as previously demonstrated (Reiniati *et al.*, 2017; Lin and Dufresne, 2014). It is also mechanically strong and characterized by high stability in vivo, owing to the absence of enzymes that can break its backbone. Because of these and other beneficial properties, BC was proposed as possible scalable and cost-effective biomaterial for several applications, including artificial blood grafts, wound dressings, or artificial skin (Hickey and Pelling, 2019; Torgbo and Sukyai, 2018; Esa *et al.*, 2014). Nevertheless, due to its high stability, the biodegradability of cellulose is very low and so it is its biological activity after implantation. Recent studies tried to investigate possible approaches to control and tailor the degradability of cellulose and enhance its properties for its application as bone tissue engineering scaffolds. The combination with additional polymers (e.g., chitosan, gelatin, fibroin, PEG) (Chakrabarty and Teramoto, 2018) and the use of biomolecules were both explored (e.g., osteogenic growth peptide, vascular endothelial growth factor) (Courtenay *et al.*, 2018). However, the main strategy adopted seems to be the fabrication of biocomposites using graphene oxide (Luo *et al.*, 2018), carbon nanotubes (Ioniță *et al.*, 2018) and, above all, hydroxyapatite (Saska *et al.*, 2011). HA fillers can be introduced into bacterial cellulose mainly via three routes: (1) in situ, that is by adding HA during bacterial synthesis, (2) by impregnation or (3) by dissolution of BC and subsequent solvent casting (Sharma *et al.*, 2019). Research performed so far on HA-bacterial cellulose composites has shown how this class of composites can effectively create an environment that promotes cell adhesion and migration, fostering a well-integrated growth of bone without significant immune response or chronic inflammation (Saska *et al.*, 2011).

Another widely used polysaccharide in bone tissue engineering is alginate, second only to chitosan and its derivatives. Alginate is composed of a random sequence of guluronic and mannuronic acid monomers. It is obtained from seaweed, brown algae in particular (e.g., several species of *Laminaria*, *Ascophyllum nodosum*, and *Macrocystis pyrifera*) which are highly available at low cost (Lee and Mooney, 2012). The purification process consists of an alkali extraction treatment, filtration and precipitation of alginate by CaCl_2 . The alginate calcium salt can be converted into alginic acid through a treatment with HCl (Dusseault *et al.*, 2006). Alginate is biodegradable, biocompatible, non-toxic and non-immunogenic. It can also be easily processed into hydrogels, microspheres, microcapsules, sponges, foams and fibers (Lee and Mooney, 2012). Many of these fabrication techniques rely on the property of alginate of being physically crosslinkable in presence of divalent cations, most interestingly calcium ions. In fact, the polysaccharide chains can organize themselves around the cations to form a so-called egg box network (Li *et al.*, 2007). Alginate is also versatile in terms of chemical modifications thanks to carboxylic moieties present at each monomer. Chemical functionalization can be used to tailor biodegradability, mechanical properties, gelation kinetics or cell behavior, among other properties. On the downside, alginate tends to resist protein adsorption upon contact with body fluids and impedes cell adhesion, a property known as antifouling. Chemical modification and composite fabrication are two main strategies used to overcome this characteristic of the polysaccharide (Venkatesan *et al.*, 2014, 2015). Composites of alginate with bioactive glass (Mishra *et al.*, 2009), calcium silicates (Wu *et al.*, 2011), TiO_2 (Naik *et al.*, 2016) and hydroxyapatite (Lin and Yeh, 2004) all proved to be viable options to increase the mechanical properties, bioactivity and cell response of pure alginate.

For the design of injectable bone fillers for tissue regeneration, pectin and its composites are the natural materials of choice (Munarin *et al.*, 2011; Lara-Espinoza *et al.*, 2018). Pectin is a polysaccharide similar to alginate, but with a more complex structure, comprising several types of oligosaccharide monomers based on galacturonic acid. It shares with alginate the ability to form an egg-box structure in presence of calcium ions, but the transition between crosslinked and soluble pectin forms can be modulated easier and without harsh conditions (e.g., high temperature or pH) by controlling the presence of counter ions (e.g., sodium), making pectin an ideal choice for tunable drug or cell carriers. In addition, certain groups found in pectin, such as rhamnogalacturonans (disaccharides of galacturonic acid and rhamnose with various side chains), were confirmed to have an influence in determining the beneficial properties of the overall material (Sousa *et al.*, 2015; Mikshina *et al.*, 2015). For instance, pectin was found to have an ability to trigger growth and differentiation of mammalian bone cells proportional to its content short chain rhamnogalacturonan moieties (Munarin *et al.*, 2011; Park *et al.*, 2013). Finally, it was demonstrated that pectin-based gel

microspheres physically crosslinked with calcium ions can be bioactive, promoting biomineralization by increasing the nucleation rate of the bone mineral phase (Munarin *et al.*, 2011).

Starch, or amyllum, is another relevant natural polysaccharide used as biomaterial (Salgado *et al.*, 2004). It has a very simple structure of repetitive glucose units linked by glycosidic bonds, either in a linear helix (amylose, 20–25 wt%) or in a branched fashion (amylopectin, 75–80 wt%). Starch is produced by most green plants as a form of energy storage and, as such, is highly available at low cost, making it an ideal candidate for scalable, environmentally friendly biomedical applications. In fact, it was proposed as an alternative to current polymers used in tissue engineering. Thanks to its adequate mechanical and degradation properties, starch is a potential candidate in the development of bone fillers, drug delivery carriers and tissue engineering scaffolds (Pacheco *et al.*, 2018). It also has promising biological properties: it is non-toxic, it does not cause excessive inflammatory responses and it supports the growth and proliferation of osteoblasts with physiological-like protein expression (Salgado *et al.*, 2004; Gomes *et al.*, 2001, 2002). In parallel, the lack of bioactivity can be overcome preparing composites of starch with HA as filler (Mirab *et al.*, 2018).

Polyhydroxyalkanoates

Polyhydroxyalkanoates (PHA) are another family of aliphatic polyesters (Basnett *et al.*, 2017). They are naturally synthesized by microorganisms, mainly bacteria, cultured in presence of unbalanced nutrient concentrations. Some relevant examples of this class of polymers are poly-3-hydroxybutyrate (PHB), copolymers of 3-hydroxybutyrate and 3-hydroxyvalerate (PHBV), poly-4-hydroxybutyrate (P4HB), copolymers of 3-hydroxybutyrate and 3-hydroxyhexanoate (PHBHHx) and poly-3-hydroxyoctanoate (PHO) (Goonoo *et al.*, 2017; Chen and Wu, 2005). Similarly to saturated poly- α -hydroxy esters, these polymers are biodegradable through hydrolysis, thermoplastic and highly processable (Basnett *et al.*, 2017). Their unique synthesis route, together with high processability and tailorability, make them very attractive candidates for the development of biomedical devices and tissue engineering scaffolds. Their use as matrix for the fabrication of biocomposites has been extensively investigated, with a particular focus on the combination between PHAs and hydroxyapatite (Ng *et al.*, 2019). High HA loading was however found to be not ideal due to lack of interaction between the two phases of the composite (Misra *et al.*, 2006). Other approaches include the use of (1) wollastonite (Li and Chang, 2005b), owing to its high mechanical properties; and (2) bioactive glasses, which thanks to their alkaline degradation products can help controlling hydrolysis and reducing possible inflammation. One strength of PHAs is their high tailorability depending on the desired application; they can be blended, surface modified or combined with other polymers (Rezwan *et al.*, 2006). The fabrication of composites is also a viable and highly explored route. In particular, blending among different types of PHAs is known to be a very effective strategy to dramatically adapt material properties and biocompatibility to specific needs (Chen and Wu, 2005; Doi *et al.*, 1995). Compared to other polyesters, PHAs seem to present fewer concerns in terms of their degradation. For instance, in a notable *in vivo* example, PHB was correlated with the induction of favorable response from bone tissue without evidence of chronic inflammatory response even after 12 months from implantation (Doyle *et al.*, 1991). During the whole implantation period, the material did not suffer major structural failures and promoted the formation of new highly organized bone tissue. However, the industrialization of this very promising family of materials is jeopardized by their limited availability and the difficulty of their extraction from the raw bacterial culture product. This fabrication step can be time-consuming and expensive, often requiring high quantity of halogenated solvents. To date, PHAs extraction seems to be a major bottleneck for the industrial scale-up and the possibility to achieve high throughput production of these polymers (Chen and Wu, 2005; Verma *et al.*, 2003). Nevertheless, the fabrication of composites with PHAs is already widely explored using mainly HA (Tong *et al.*, 2010), bioactive glasses (Zhou and Yu, 2014), wollastonite (Li and Chang, 2005a,b) and metal oxides (Anžlovar *et al.*, 2018).

Scaffold Fabrication Techniques and State of the Art

In addition to the bulk properties of the material used, tissue engineering scaffolds have to be designed bearing in mind another important characteristic: their morphology. A complex and hierarchical 3D porous architecture is fundamental to guarantee the homogeneous development of new tissue for a number of reasons. First of all, micrometric pores (circa 400 μm) allow cell infiltration through the scaffold, both upon seeding and in second instance during proliferation and migration. Additionally, wide pores support the spreading of vessels, the diffusion of nutrients, the removal of metabolic waste and the even distribution of newly formed extracellular matrix (ECM) during tissue development (Perez and Mestres, 2016). Smaller pores and roughness are thought to influence cell behavior, too. Specifically, surface topographical features can stimulate cell membrane integrins and other receptors, ultimately regulating cellular processes such as migration, proliferation and gene transcription (Nguyen *et al.*, 2016). The presence of combined hierarchical micro- and nanometric topographical features is considered a fundamental requirement for successful tissue engineering scaffolds and it has been studied in-depth for decades (Jeon *et al.*, 2014; Jin and Kim, 2014; Gritsch *et al.*, 2017). In particular, a plethora of material processing techniques have been optimized and are currently available to fabricate porous biocomposite scaffolds. A recent critical review by Garg *et al.* (2012) offers a comprehensive overview about the pro and cons of scaffolds and their respective fabrication techniques (Fig. 5).

Scaffold fabrication techniques are usually classified using mainly two rationales: (1) top-down and bottom-up methods, or (2) traditional and non-traditional fabrication techniques (Subia *et al.*, 2010). In particular, the first classification is based on the nature of the fabrication approach: top-down methods are processes that remove portions of the initial material bulk to obtain the final structure (e.g., particulate leaching, freeze-drying). Conversely, bottom-up approaches are the ones in which the structure is

Fig. 5 The physiological structure of cancellous bone (A) compared to the typical morphologies obtained with current scaffold fabrication techniques: solvent casting/particulate leaching (B), microsphere sintering (C), thermally induced phase separation (D), supercritical CO₂ foaming (E), electrospinning (F), melt electrospinning writing (G) and 3D printing (H). progressively built using smaller building blocks (e.g., 3D printing, electrospinning). Often a combination of the two approaches leads to the best results as it allows the simultaneous formation of features at different resolutions and thus the creation of a more complex and hierarchical structure (Biswas *et al.*, 2012). This makes it often hard to conclusively classify a scaffold fabrication technique into one of the two categories. In the following sections, current main fabrication techniques for the preparation of biocomposite scaffolds for tissue engineering are presented and discussed in terms of their benefits and disadvantages.

Solvent Casting/Particulate Leaching

The most traditional and straight-forward technique to prepare composite scaffolds is probably solvent casting (SC). In this process, a polymer is dissolved in a proper solvent, mixed with the filler to create a homogeneous suspension and cast in a desired mold for solvent evaporation. This method allows for the fabrication of bulk films, but it can also be performed in combination with a particulate leaching (PL) step to obtain porous features. In a typical top-down SC/PL method, a porogen agent insoluble in the solvent is added during the preparation of the mixture and leached from the scaffold by dissolution in a second solvent that dissolves the porogen but not the main composite structure. SC/PL is an inexpensive and widely studied technique to readily prepare tissue engineering scaffolds without the need for a complex apparatus. However, it has several disadvantages, including limited control of pore distribution and interconnectivity and extensive use of solvents, which could potentially remain in the final product and cause toxicity. Solvent consumption can be reduced if the solvent blending between polymer and filler is replaced by melt blending: the filler and the porogen are mixed with the molten polymer. This method successfully avoids the use of solvents to dissolve the polymer for the matrix. However, it does not overcome the limits of this technique in terms of porosity control and solvent consumption during the leaching process. The state of the art on SC/PL has been recently reviewed by Prasad *et al.* (2017).

Microsphere Sintering

Microsphere sintering is a traditional bottom-up scaffold fabrication technique to create a porous interconnected 3D construct starting from polymeric microspheres produced with various methods (e.g., emulsification, polymer spraying) and sifted to a desired size range (Singh *et al.*, 2008). During this step, particles of a bioactive filler can be dispersed within the polymer in order to create composite microspheres. Microsphere sintering takes its name from its similarity to ceramic sintering: the polymer microspheres are poured in a three dimensional mold, compacted and heated slightly above their glass transition temperature without applying pressure in order to partially fuse them and create a porous network. Subcritical CO₂ was also used as an alternative sintering agent (Singh *et al.*, 2010). The structures that can be obtained by this technique are well interconnected. However, high porosity (> 70%) as well as fine control over the final morphology are hard to achieve (Chu and Liu, 2008). Nevertheless, the mild processing conditions of microsphere sintering still make this technique very interesting and particularly suitable for the preparation of scaffolds with a release capability for therapeutic molecules. In fact, since the drug can be loaded homogeneously within the polymer during microsphere preparation, the incorporation efficiency will be higher than the one obtained by simple adsorption and, likewise, the delivery will be better controlled over time (Singh *et al.*, 2008). The drug delivery potential of microsphere sintering determined that PLGA is the principal polymer used for this technique. Composite TiO₂/PLGA porous scaffolds prepared using this technique were proposed by Wang *et al.* (2010) using composite microspheres prepared by emulsion in PVA. The sintering was performed at 90°C for 2 h. The resulting constructs showed improved cell adhesion, probably due to a protein selection phenomenon mediated by TiO₂, which favored fibronectin and bovine serum albumin adsorption on the surface of the scaffold, promoting in turn the interaction between the biomaterial and the membrane integrins of osteoblasts. The filler also regulated the activity of osteoblasts, promoting ALP activity and calcium secretion.

Finally, microsphere sintering can also be used to prepare a negative sacrificial template to combine with SC/PL (Bossard *et al.*, 2018). Briefly, a three-dimensional structure is prepared as described above using an easily leachable material. A suspension of polymer and filler is then infiltrated through the cavities of the sintered construct. Infiltration can be vacuum-aided or improved by centrifugation, among others. After complete evaporation of the solvent, the microspheres can be leached out using a proper solvent to obtain a composite cast of the negative template. The combination of microsphere sintering with SC/PL was demonstrated fabricating porous hybrid scaffolds consisting of PCL and 75S25C BG. Using this combined technique, it was possible on one hand to obtain a more controlled and interconnected pore distribution than simple SC/PL, while at the same time achieving higher porosity than simple sintering (Bossard *et al.*, 2018). The scaffolds were also biologically tested *in vitro* and *in vivo*. Results showed that they can promote osteoblast adhesion and differentiation *in vitro*. In parallel, micro-computed tomography (μ CT) measurements of *in vivo* implantation demonstrated that PCL/BG resulted in higher bone ingrowth compared to a commercial xenograft used as control. Histological data also revealed ongoing vascularization and bone remodeling, confirming that the scaffolds offer a promising alternative to current technologies (Granel *et al.*, 2019).

Thermally Induced Phase Separation (TIPS)

Thermally induced phase separation (TIPS) identifies a group of traditional top-down processes to fabricate porous composite scaffolds that overcome the porosity constraints of previously described methods (Mannella *et al.*, 2015; Barroca *et al.*, 2010; Helen *et al.*, 2007). Typically, TIPS consists of the solvent blending of a polymer with an insoluble inorganic filler and subsequent rapid

quenching of the mixture at temperatures below the limit of solubility of the polymer. This quick transition solidifies the solvent and causes a phase separation forcing the polymer and the particles into the remaining interstitial spaces. TIPS is then coupled with a freeze-drying step to sublimate the solvent and obtain a highly porous composite scaffold with full pore interconnectivity (Maquet *et al.*, 2004). The pore distribution of scaffolds obtained by TIPS/FD is characterized by a typical strong anisotropy: the pores follow the direction and shape of solvent crystals that solidified according to the applied gradient of temperature (Barroca *et al.*, 2010). This determines that controlling the freezing parameters has great impact on the size, shape and direction of the pores, allowing to ultimately tailor the final structure of the scaffold to the specific application need. The polymer, the solvent, the ratio between the two and the presence of third moieties in the mixture are other relevant parameters that determine the morphology of the construct. A porogen can also be added, combining TIPS/FD with PL to obtain a highly hierarchical porosity with maximized interconnectivity (Kim *et al.*, 2012a). TIPS/FD was widely applied to the processing of PDLLA-based composite scaffolds. Rich literature is available on the phase separation fabrication of PDLLA/Bioglass® porous scaffolds and their characterization in terms of porous morphology, mechanical properties, in vitro short and long term degradation, bioactivity and cell culture with different cell phenotypes (Blaker *et al.*, 2005; Verrier *et al.*, 2004; Maquet *et al.*, 2003; Blaker *et al.*, 2011). Similar scaffolds were used to investigate the ability of these constructs to promote adhesion, proliferation and ECM-secretion of primary annulus fibrosus cells seeded on them, in view of their application as treatment for damaged intervertebral disc. Remarkably, the results showed that PDLLA/Bioglass® porous scaffolds provide the adequate cues for cells, enhancing their proliferation and promoting the production of glycosaminoglycans and collagens of both types I and II. Above all, type II collagen is particularly important for the formation of physiological-like cartilage tissue (Bernhard and Vunjak-Novakovic, 2016). The technique is also highly promising for the processing of chitosan/hydroxyapatite composites. As demonstrated by Lei *et al.* (2017), HA disperses with particularly high homogeneity within chitosan solutions. The authors prepared a Sr-HA/chitosan nanocomposite with three-dimensional interconnected macroporosity (100–400 μm) which gave remarkably positive results when biologically tested in vitro. Sr-HA nanocrystals were found to significantly improve the proliferation and osteogenic differentiation of human bone marrow mesenchymal stem cells. In particular, the release of strontium ions from the composite enhanced ALP activity, ECM mineralization and the expression of osteogenic-related COL-1 and ALP genes. The authors also highlighted the presence of an optimum level of strontium substitution at which a synergic effect between strontium and calcium ions is established, leading to the strongest combination of bioactive and osteogenic properties (Lei *et al.*, 2017).

Supercritical CO₂ Foaming

Although it is widely used in tissue engineering thanks to its versatility, TIPS has the disadvantage of relying on solvents that present concerns in terms of toxicity and waste management. For these reasons, in recent years authors suggested foaming by means of supercritical fluids, and of supercritical CO₂ in particular, as a promising strategy to reduce the use of solvents (Reverchon *et al.*, 2008; Kim *et al.*, 2012b). Thanks to its unique physical properties, non-toxicity, low cost, liquid-like density, gas-like viscosity and very low surface tension, supercritical CO₂ is an ideal medium to impart porosity to polymers. Furthermore, since the supercritical temperature and pressure values are relatively mild ($T_c = 31.5^\circ\text{C}$ and $P_c = 75.8\text{ bar}$), this process can be used to impregnate materials with biomolecules, such as growth factors, that would be degraded or denatured by other fabrication techniques (Davies *et al.*, 2008). In a typical supercritical CO₂ foaming protocol for a PLGA/ β -TCP composite (Yang *et al.*, 2010), the desired amount of polymer and filler are mixed, put in a mold and compressed. The filled molds are then fed into the reactor. Afterwards, the temperature is raised, the reactor chamber purged with N₂ and then filled with CO₂ at a desired pressure. Temperature/pressure conditions are kept constant over a period of time to allow foaming and finally the chamber is vented. Li *et al.* (2019) used this type of protocol to prepare porous composite scaffolds with a PLGA matrix and a mesoporous bioactive glass (MBG, composition 79.5wt% SiO₂, 14wt% CaO and 6.5wt% P₂O₅) particulate filler. The authors used the advantage of the mild processing conditions of supercritical CO₂ foaming to also introduce the proangiogenic lipid FTY720. With a simultaneous sustained release of the lipid and ions from the MBG, the composite scaffolds were found to favor cell adhesion and proliferation, but most importantly to promote in vitro osteogenic differentiation of bone marrow stromal cells while also upregulating the expression of HIF-1 α via the activation of the Erk1/2 pathway, a key element for the mediation of osteo- and angiogenesis. These promising results were further scrutinized in vivo in a critical-sized rat calvarial bone defect. Vascularized bone regeneration was observed in presence of FTY/MBG/PLGA scaffolds, in particular an increase in the formation of type H new vessels was observed in newly formed bone tissue, possibly as a consequence of a synergistic effect between FTY720 lipid and therapeutic ions release. This achievement is particularly relevant, since it is well-known how effective bone regeneration must be coupled with equally effective angiogenesis in order to obtain physiological-like new tissue. Supercritical CO₂ processing is an environmentally friendly technique with a high potential for the development of tissue engineering porous scaffolds with controlled drug release. In addition, protocols for supercritical CO₂ foaming are very simple and reproducible, which is a strong asset in view of clinical application and commercialization. However, compared to TIPS, it requires specific equipment to be performed (e.g., a high pressure reactor) and, as such, has higher associated costs (Carfi Pavia *et al.*, 2013).

Electrospinning

Beginning in the early 1990s, many research groups started to investigate the suitability of a novel technique for the fabrication of non-woven fibers with significantly smaller diameters compared to traditional fiber fabrication techniques (Jiang *et al.*, 2014;

Huang *et al.*, 2003). The technique had been popularized as electrospinning by Reneker and Rutledge (Doshi and Reneker, 1995) and quickly gained relevance as an important approach to fabricate scaffolds for the regeneration of many tissues, including skin, muscle, nerves, bone and blood vessels (Agarwal *et al.*, 2008). The rapid spreading of interest over electrospinning in the biomedical field is due to the high potential of this technique to mimic the complex range of morphological features of the natural ECM (Bagbi *et al.*, 2018). In fact, a typical electrospun structure features well interconnected porosity and nano- and microscale topographical cues that were demonstrated to effectively guide cell proliferation and migration and facilitate the formation of new functional tissue (Tong *et al.*, 2010). Electrospinning consists of applying a high-voltage electric field (10–20 kV) between the needle of a syringe delivering a polymer solution and a collecting plate in front of it. This electric force overcomes the surface tension of the droplet on the top of the needle creating a so-called Taylor cone and a thin polymer jet diffusing from the needle to the collector. While the jet elongates and thins, the solvent evaporates and forms polymer fibers. Owing to its high versatility, with electrospinning it is possible to achieve diverse fiber features using a relatively simple apparatus. This is because the properties of electrospun constructs can be radically influenced by carefully adjusting process parameters: solution (i.e., viscosity, conductivity, surface tension), electrospinning (voltage, flow rate, needle-collector distance) and ambient parameters (temperature, humidity, air flow) among others (Jiang *et al.*, 2014; Kolbuk *et al.*, 2015). With specific sets of these properties it is possible to refine fiber topography, obtaining for instance porous or hollow fibers. The shape of the collector and its relative movement to the needle also play an important role, allowing to control fiber direction and to fabricate non randomized structures, such as aligned fibers (Subramanian *et al.*, 2011; Jose *et al.*, 2012) or hollow cylinders (Marelli *et al.*, 2012a). In recent developments, electrospinning was also combined with sol-gel chemistry for the spinning of inorganic sols and the fabrication of fully inorganic fibers (Choi *et al.*, 2003) or polymer/ceramic hybrids, as recently reported by Pirzada *et al.* (2012), who successfully produced silica/poly (vinyl alcohol) hybrid electrospun fibers. Most importantly, electrospinning is often combined with a composite approach. In fact, the addition of particles of a second phase was confirmed as a viable strategy to prepare non-woven fibrous composite scaffolds with enhanced properties, especially in terms of bioactivity (Agarwal *et al.*, 2008; Labbaf *et al.*, 2018; Liverani *et al.*, 2017; Noh *et al.*, 2010; Liverani *et al.*, 2014). For instance, various types of bioactive glass were solvent mixed with PCL using class III benign solvents (formic and acetic acid) and electrospun. The tested BGs included microparticles of commercially available Vitryxx® (45wt % SiO₂, 24.5wt% CaO, 24.5wt% Na₂O and 6wt% P₂O₅) and nano-sized 45S5 BG (Liverani *et al.*, 2018) as well as custom formulations of mesoporous bioactive glasses (MBGs), such as calcium-containing silica nanoparticles (MCM-41) (Liverani *et al.*, 2017) and silver-doped MGB (composition 77wt% SiO₂, 18.5wt% CaO, 1.5wt% P₂O₅ and 3wt% Ag₂O) (Ciraldo *et al.*, 2018b). Other relevant combinations reported for electrospinning are PHBV/HA (Ito *et al.*, 2005), gelatin/ZnO (Münchow *et al.*, 2015) and fibroin/HA (Kim *et al.*, 2014a), among many others (Baji and Mai, 2017). The composite approach applied to electrospinning is progressively gaining importance as an effective strategy to introduce the advantages of bioceramics into the ECM-like morphology of polymer fiber mats. Liverani *et al.* (2018) confirmed that embedding BG particles in PCL/chitosan fibers did not hinder the bioactivity of the former, while Labbaf *et al.* (2018) tested a similar PCL/BG system using a sol-gel derived 58S formulation. The authors found that PCL/58S could be a promising candidate biomaterial for dental pulp tissue engineering, given that dental pulp stem cells were found to optimally adhere and proliferate on the substrate while mineralization, measured by alizarin red, was significantly increased compared to a positive control (i.e., tissue culture polystyrene, TCPS).

Additive Manufacturing (AM)

The term Additive Manufacturing (AM), also known as Solid Free-form Fabrication (SFF) or Rapid Prototyping (RP), identifies a broad category of both top-down and bottom-up non-traditional techniques for scaffold fabrication (Hutmacher, 2006; Li *et al.*, 2015; Calignano *et al.*, 2019). In AM, a construct is precisely recreated layer by layer following a previously developed computer aided design (CAD). There are countless AM approaches, usually divided into seven categories: material extrusion, material jetting, binder jetting, sheet lamination, VAT photo-polymerization, powder bed fusion and direct energy deposition.

Currently (Li *et al.*, 2015; Singh and Ramakrishna, 2017), the most studied methods to manipulate polymer-based bio-composites are either laser-based techniques such as (1) stereolithography (SLA), in which fluid resin is first evenly distributed on a platform, irradiated with a desired pattern, photo-polymerized, recoated with the following layer and so on; or (2) selective laser sintering (SLS), where a focused laser heats powder deposited layer by layer, causing sintering of the particles and formation of a desired pattern. Alternatively, nozzle-based approaches are explored, mostly (3) fused deposition modeling (FDM), a technique based on spatially-controlled extrusion in the three dimensions, (4) solvent-based 3D printing, using for example fibroin and MBG (Du *et al.*, 2019) or polycaprolactone and 13-93B3 (Kolan *et al.*, 2019), and (5) bioplotting, similar to 3D printing, but with ink dispensing inside a liquid medium with matching density that allows for fabrication without need of additional support. In contrast to other AM techniques, bioplotting is more versatile and can be used to process a wide variety of different materials, as well as to directly print cells within the ink. Among these, one of the principal candidates is alginate. Alginate-based bioinks are particularly relevant owing to the possibility to precisely tailor the gelation process in presence of divalent cations (see paragraph “Polysaccharides: chitosan, cellulose, starch, alginate, pectin”). Generally, calcium sulfate (CaSO₄) is used as source of calcium for crosslinking, owing to its ideal solubility compared to other calcium salts (e.g., CaCl₂), resulting in higher working times (Lee and Mooney, 2012). A bioactive filler, usually hydroxyapatite (Gao and Cui, 2016), is added in order to increase both the mechanical and biological properties of the biopolymer. To improve the homogeneity and the dispersion of the filler proper dispersants are usually added to the ink, for instance poly(vinyl alcohol) (Bendtsen *et al.*, 2017) or sodium citrate (You *et al.*, 2018). Typical

results show these setups are effective in protecting cells during the printing process and are characterized by good biological performance. You *et al.* (2018), for instance, demonstrated the ideal properties of an alginate/hydroxyapatite bioprinted scaffold for its application in osteochondral tissue engineering: the presence of the bioactive filler homogeneously dispersed within the polysaccharide (thanks to the addition of sodium citrate) was linked to increases in ALP activity, mineralization and collagen type X secretion by chondrocytes seeded during printing. Scaffolds were also subcutaneously implanted *in vivo* in a murine model, confirming the higher mineralization potential of composites compared to alginate alone (Fig. 6).

Thanks to its ability to crosslink *in situ*, PPF is also a promising candidate for scaffold additive manufacturing. In a recent case study, Trachtenberg *et al.* (2017) investigated the combination of this attractive biodegradable polymer with HA nanoparticles, aiming to obtain an accurate fabrication process resulting in scaffolds with robust compressive mechanical properties. Their results confirmed that it was possible to obtain PPF/HA 3D printed porous scaffolds with complete interconnectivity, measured by μ CT. Most remarkably, the process permits fine tailoring of the amount of HA layer-by-layer by simply varying the composition of the ink. This in turn results in scaffolds with a HA gradient that can better mimic the structure of physiological bone, and especially the one of the osteochondral tissue at the interface between bone and cartilage. Buyuksungur *et al.* (2017) also explored the potential of PPF in biomedical additive manufacturing, in particular using fused deposition modeling. The polymer was printed in combination with PCL and nano-sized HA (nHA) in order to improve and tailor the hydrophilicity of the scaffolds. Results confirmed that nHA significantly increased the compressive modulus and promoted cell adhesion compared to pure PCL. The addition of PPF, in parallel, improved the proliferation rate of bone marrow stem cells seeded onto the scaffolds. Furthermore, the composite scaffolds showed improved mineralization (alizarin red assay) and ALP activity as well as increased expression of relevant genes for osteogenesis (COL1 and RUNX2). These variations were mostly linked to the presence of the bioceramic filler. *In vivo* characterization and histological observations in a rabbit model confirmed the potential of PCL/PPF/HA composite scaffolds: improved tissue regeneration and mineralization were assessed for the biocomposites compared to a PCL control and, most remarkably, the stiffness of the final tissue/scaffold construct was found to be similar to the one of healthy bone samples.

AM techniques can also be used indirectly to prepare a sacrificial negative template that will be then infiltrated with a desired scaffolding biomaterial and made porous by leaching of the printed material (Calignano *et al.*, 2019). The indirect approach has the strong benefit of allowing the use of polymers optimized specifically for AM without the constraint of its biological properties (Calignano *et al.*, 2019). Regardless of the specific method, both direct and indirect AM are continuously gaining more resonance as effective ways to fabricate scaffolds thanks to their unique benefits of total control over scaffold architecture, high accuracy in structure reproduction and virtually complete interconnectivity. This can possibly lead to customized design of scaffolds, depending on the need of each patient (Egan, 2019). However, research still has to be performed in particular to expand the portfolio of available materials for these techniques as well as the current resolution limitation within micrometric ranges (Dalton *et al.*, 2015).

Melt Electrospinning Writing

Recently, a new technique has been proposed, which combines the versatility and accuracy of additive manufacturing techniques with the higher resolution of traditional electrospinning: melt electrospinning writing (MEW), described by its creators as a technique to bridge the gap between solution electrospinning and direct writing additive manufacturing processes (Muerza-Cascante *et al.*, 2014; Brown *et al.*, 2016). It consists of the melt electrospinning of polymer fibers toward an automated stage collector that moves according to the speed of the melt electrospinning jet and controls where fibers deposit. MEW is a high resolution and high throughput AM approach that allows fabrication of highly porous fiber scaffolds with submicrometric morphological features and total control on the final structure of the construct (Wunner *et al.*, 2018; Hrynevich *et al.*, 2018; McColl *et al.*, 2018; Wunner *et al.*, 2019). Due to its recent development, though, not many polymers have been demonstrated to be suitable for MEW. The recognized benchmark polymer for this technique is polycaprolactone (McColl *et al.*, 2018; Hochleitner *et al.*, 2015). This polymer was used alone, but also combined with bioactive inorganics, for the fabrication of composites for tissue engineering. By adding strontium-doped bioactive glass to PCL fibers, for instance, it was possible to induce ion release during cell culture, ultimately triggering the deposition of HCA on the scaffolds while enhancing the adhesion and proliferation of MC3T3-E1 pre-osteoblasts *in vitro*, compared to PCL-only scaffolds. Results also highlighted how cells had increased alkaline phosphatase activity as well as improved differentiation toward the osteoblast phenotype, demonstrating their potential in the development of artificial bone grafts.

Current MEW research is extending the range of available polymers to produce scaffolds, using for example poly(2-ethyl-2-oxazoline) (Ren *et al.*, 2014), poly(L-lactide-*co*- ϵ -caprolactone-*co*-acryloyl carbonate) (Chen *et al.*, 2016) or poly(urea-siloxane) (Hochleitner *et al.*, 2018). More remarkably, block polymers of racemic PDLLA and poly(ethylene glycol) were developed to be processed into biocomposite MEW structures, as demonstrated by Hochleitner *et al.* (2015). PLA-PEG-PLA has been successfully melt electrospun in combination with melt-derived micro-sized 45S5 Bioglass®.

Summary and Current Challenges

Properties of Bioactive and Biodegradable Polymer-Based Composites

Biocomposites consisting of a biodegradable polymeric matrix and an inorganic bioactive phase are a major class of biomaterials studied in the past two decades for diverse applications in medicine, in particular in the field of tissue engineering. Conventional

Fig. 6 Diagram summarizing the different types of additive manufacturing techniques currently in use and the materials they are particularly relevant for each method.

Fig. 7 Elastic modulus versus compressive strength ranges of biodegradable polymers, bioactive ceramics, both dense and porous, and composites thereof. Porosities of the porous scaffolds are $>75\%$ and mostly interconnected. Figure is adapted from reference Rezwan, K., Chen, Q.Z., Blaker, J.J., Boccaccini, A.R., 2006. *Biomaterials* 27, 3413–3431, with permission of Elsevier.

material processing techniques have been adapted and improved with the specific aim of incorporating bioactive fillers into three-dimensional, porous and interconnected polymeric networks. These constructs are specifically engineered to support the growth of new tissue, promote its mineralization (i.e., bioactivity) and degrade with properly tailored kinetics. This chapter offered a summary on the main current biodegradable polymers, inorganic bioactive fillers and fabrication methods used, together with an overview of the current achievements and state of the art in the field. Nevertheless, several challenges remain to be tackled. In particular, Rezwan *et al.* (2006) identified four major materials science trends/challenges that current and future research should focus on in order to advance laboratory research to clinically relevant devices. First of all, in spite of all the extensive research developed for decades on the topic, the mechanical strength of most artificial scaffolds is still significantly lower than that of cancellous bone and even more in the case of cortical bone. This determines strong limits in both the size and type of bone defects that can be treated to date. When comparing the elastic modulus and the compressive strength of dense bioactive ceramics, biodegradable polymers and monophasic as well as composite porous scaffolds to those of cancellous and cortical bone, it can be observed that the required properties are reached by few dense polymers and bioactive ceramics. Porous scaffolds, on the other hand, are weaker than bone (at least one order of magnitude) and have generally insufficient mechanical strength. This mismatch between the bulk properties of materials and composites and the properties of their porous structures is one of the current key limitations of this type of tissue engineering scaffolds. As discussed in this here, the composite approach is usually an effective strategy to improve the mechanical properties of scaffolds. However, the increase is often lower than desired, most probably due to low interfacial bonding between the two phases. The use of surface functionalizations and/or surfactants are main strategies under investigation to achieve further improvement in scaffold mechanical properties (Fig. 7).

Secondly, the surface properties of scaffolds should be engineered in order to optimize cell response. Chemical modifications are extensively investigated and used to modify and improve the biological performance of currently developed tissue engineering constructs. Cell response can be tailored and promoted by altering the protein adsorption behavior of materials when in contact with body fluids (e.g., antifouling), as well as by adding new functionalities that can beneficially communicate with cells (for instance, integrins, laminins, RGD proteins and several growth factors including vascular endothelial growth factor, bone morphogenetic proteins, transforming growth factor beta and insulin-like growth factor). Grafting biologically active moieties onto biomaterials and especially biocomposites is a vast and highly promising field that has given successful results so far, as reported in previous reviews (Tallawi *et al.*, 2015; Mas-Moruno, 2018). From a materials science point of view, the use of such biomolecules introduces limits in terms of processability: harsh conditions such as high temperatures, extreme levels of pH and even the presence of certain moieties (e.g., calcium) can degrade the biomolecule and make it inactive. This will have to be taken into account when designing composite materials containing proteins and growth factors. For instance, microsphere sintering and sol-gel based techniques are considered to be highly promising fabrication methods for GF-containing scaffolds.

Finally, the long-term degradation and mechanical behavior of composites as well as their *in vivo* and preclinical biological performance need further investigation. In particular, better analytical models have to be developed in order to study and predict the behavior of biocomposites once implanted in a patient. In addition to that, in recent years another trend has gained importance: stem cell encapsulation/delivery within the composite scaffold, in particular in relation to additive manufacturing techniques, which seems to be a promising strategy to achieve better tissue regeneration compared to acellular approaches (Gasperini *et al.*, 2014).

The Advantage of Nanocomposites

The previous paragraph has discussed possible future trends in the optimization of the properties of conventional biocomposites. An alternative route to enhance the properties of this class of materials increased in popularity in recent years: the development of

nanocomposites. The use of nanoparticles and nanofibers over conventional micro-sized fillers has recently become feasible by advances in synthesis methods, especially in sol-gel based techniques for the fabrication of nanoscale bioactive glass. The advantages of bioactive glass nanoparticles or nanofibers over micro-sized ones have been demonstrated very promising, thanks to their larger surface area, increased solubility and reactivity (Misra *et al.*, 2008). For instance, Caridade *et al.* (2013) observed how the inclusion of nano-sized Bioglass® in a chitosan matrix resulted in higher bioactivity, and thus higher surface reactivity, than control composites with a conventional micron-sized filler. In addition, nano-sized fillers introduce nanotopographic surface features in composite scaffolds, increasing their hierarchical porosity and roughness and, in turn, optimizing the response of cells cultured on them (Gritsch *et al.*, 2017). Nanoscale surface features can in fact promote cell adhesion, motility and differentiation. Studies have also confirmed that nanotopography can enhance selective protein adsorption of fibronectin, vitronectin and several other peptides associated with successful cell attachment (Verma *et al.*, 2011; Dvir *et al.*, 2011). Furthermore, oriented topographic patterns can further guide the movement and growth of cells through contact guidance. In this way, it can be possible to obtain highly anisotropic tissues, such as tendons, nerves or muscle fibers (Nguyen *et al.*, 2016). Nanocomposites are particularly investigated for bone tissue engineering, dentistry (i.e., dentin regeneration) as well as in cartilage and osteochondral regeneration, as described in a previous review paper (Boccaccini *et al.*, 2010). The combination of biodegradable polymers, both synthetic and natural, with nanoscale bioactive fillers, bioactive glasses in particular, is emerging as a powerful strategy towards a new generation of enhanced bioactive materials with substantial advantages in terms of material homogeneity, reactivity and biological response compared to conventional composites with μm -scale fillers. The research on these materials is expected to expand in the future. In particular, increasing processing approaches for inorganic nanostructured bioactive materials will increase their possible applications. Possible identified directions of future research are the investigation on injectable osteoconductive biomaterials, thin coatings and self-assembling nanocomposites as well as the optimization of the micro/nano-scale spatial control of surface bioactivity (Boccaccini *et al.*, 2010; Gritsch *et al.*, 2017). In parallel, both in vivo response and clinical effectiveness of bionanocomposites still need to be tested and fully validated, with particular attention to be put in clarifying the health and safety concerns associated with the long-term use of nanomaterials (Alpaslan and Webster, 2014).

Concluding Remarks

Polymer-based composites consisting of a biodegradable polymer as matrix and a bioactive filler are a major class of materials used for the development of scaffolds for hard tissue repair. These materials offer a synergic combination of a glass/ceramic with tissue bonding properties (i.e., bioactive) coupled with the ease of processing of biocompatible degradable polymers formed into a three-dimensional structure. Countless materials and processing strategies have been proposed in the past decades and are currently available and still under investigation. In this chapter, the main materials available, together with the most applied and promising fabrication techniques have been listed and described. These biodegradable and bioactive biocomposites combine several key properties for their successful application in tissue engineering: interconnected porosity, ideal structure and topography, bioactivity, biodegradability and the possibility of biomolecule incorporation. It was shown how being able to accurately tailor all the several variables at play, such as materials and their processing, fabrication techniques, grafting of biomolecules and, in some cases, encapsulation of cells, is key for a successful device. However, at the same time, several limitations remain to be addressed, mainly the need for improved mechanical properties, more accurate tailoring of the cell response and better analytic tools to investigate and predict the long-term behavior of biocomposite scaffolds. Many challenges are still ahead, but with them also many opportunities for biomaterials research.

General Introduction

Bioceramics is the term for ceramics used in biological environments especially for bone or dental substitution (Paul *et al.*, 2010). Even if they are mainly used in orthopedics and dentistry, they are also used in drug delivery applications. The most commonly used ceramics are calcium phosphates (CaPs) in the form of α or β -tricalcium phosphate or hydroxyapatite, silicates like 45S5 Bioglass®, alumina, porcelain and zirconia (Bose *et al.*, 2018). The surface of these implanted materials is subject to a large kind of species from water, biomolecules to dissolved ions and also external stimuli. Typically, the integration ability of bioceramics into a biological medium is determined by the interaction between these external factors and the material surface. The ultimate goal of bioceramics engineering is to enhance as much as possible this integration of the manufactured ceramics. By consequence, it is necessary to first study and promote the interactions between the synthetic material and the body environment (Kurella and Dahotre, 2005; Soon *et al.*, 2016).

It is known that material surface properties could be really different from the bulk properties. There is always a balance when choosing an appropriate material between these two kinds of properties. A material could be totally suitable for a specific application in terms of bulk properties while its surface biological interactions are unsuitable or even incompatible. Therefore, surface modification is able to maintain the key bulk properties of the material while only modifying the surface. By this way, it is not necessary to change the bulk material to increase the biocompatibility (Kurella and Dahotre, 2005; Bose *et al.*, 2018). Moreover, even if a ceramic compound is intrinsically biocompatible, an abundance of studies all over the world proved that the surface properties and so the biointegration can be enhanced by surface modification (Soon *et al.*, 2016). Finally, the main objective of the surface modification of a biomaterial is to create a specific chemical and physical environment that offers a favorable cellular (Bose *et al.*, 2018) and bacterial response (Tuson and Weibel, 2013) in the biological medium.

Typically, the surface properties known to affect the interactions between a solid biomaterial and a biological environment are the surface energy, surface charge, wettability, surface chemistry and the surface topography (Soon *et al.*, 2016; Fig. 1).

These influential properties are discussed in more detail in the next section for all kind of biomaterials like polymers, metals, ceramics and composites. Indeed, these different materials are submitted to the same conditions into the biological environment when they are implanted. Therefore, the influence and the role of surface properties on biological interactions are quite similar for each kind of material.

Influential Surface Properties for Biocompatibility

Surface Energy

As defined by Murthy (2011), surface energy is the work required to increase unit surface area at constant temperature, pressure and composition. It is the manifestation of intermolecular forces due the unbalanced molecular forces existing with the molecules at the surface of liquid or solid. Indeed, these surface molecules are not subject to the same number of forces than the molecules inside the phase (liquid or solid) and therefore possess additional energy. When two condensed phases are in contact, the interfacial energy is defined as the additional free energy between these two phases. These surface and interfacial energies are essential due to their ability to widely influence the material behavior in different conditions. For example, the wettability, another important surface property which has an important role in determining the biocompatibility, adsorption processes and adhesion in biomaterials, is highly dependent on the surface energy and surface tension (Murthy, 2011; Van Krevelen and Te Nijenhuis, 2009).

Therefore, the modification of the surface energy by surface treatments can help to improve the biocompatibility. In several studies, it has been hypothesized that high surface energy is more appropriate for bone implants like titanium or ceramics. Higher surface energy means higher wettability which can enhance the interactions between the implant surface and the biological environment. Indeed, an increase in the cell spreading is observed on the substrates with higher surface energy (Zhao *et al.*, 2005).

Surface Charge

Obviously, electrostatic forces have a determinant role in cells attachment on biomaterials surfaces. When two different phases are in contact, this leads to some ionic interactions at the interface. The charge accumulation resulting from these interactions forms the electrostatic potential. Several parameters are used to describe this surface potential but the most used is the zeta potential (Metwally and Stachewicz, 2019). Zeta potential is defined as the potential difference between the medium and the stationary layer of fluid attached to the particle (Barba *et al.*, 2019). Even if zeta potential can be very useful, it only gives indirect information about the surface potential as it measures the net charge of material immersed in a liquid solution. Other methods like KPFM

Fig. 1 Surface properties affecting interactions between a solid biomaterial and a biological environment.

(Kelvin Probe Force Microscope), EFM (Electrostatic Force Microscope) or XPS (X-ray Photoelectron Spectroscopy) techniques can provide direct measurement of charge distribution without liquid immersion (Metwally and Stachewicz, 2019).

Several researches studied the charge impact on cells (human endothelial cells, osteoblast-like fibroblast, and neural cell). It was found that surface charge is predominant in the step of adhesion between cells and biomaterials surface and especially in the initial stages of cell attachment. In addition, its role is critical for the cell differentiation signaling. It has also been shown that positive charges are more beneficial for the cell attachment. Indeed, positive charges activate the immune system supporting tissue regeneration and the positively charged surfaces adsorb more proteins. It is not surprising because most of the existed cells and their corresponding adhesion proteins are negatively charged (Fig. 2; Lotfi *et al.*, 2013; Metwally and Stachewicz, 2019).

Therefore, surface charge can be used to control cells and enhance their attachment and proliferation. The complete study of the influence of surface potential on the cells-surface interaction could help to develop functional implantable biomaterials for different applications like regenerative medicine. For now, the different mechanisms involved in the control of cells activities via surface charge are still at an early stage of understanding. Indeed, these interactions between cells and surfaces are complex and need extended investigation in connection with other surface properties like topography, wettability and surface chemistry (Lotfi *et al.*, 2013; Metwally and Stachewicz, 2019).

Wettability

Wettability corresponds to the ease of spreading of liquid on the surface. This ability is directly related to the intermolecular forces between the phases in contact (Agrawal *et al.*, 2017). Typically, wettability can be estimated by contact angle measurements. Contact angle of the surface is defined as the angle formed by the intersection of solid-liquid and liquid-vapor interface. This angle is obtained by putting a drop of liquid on a flat material surface and by drawing a tangent along the liquid-vapor interface. The contact angle is used to represent the final shape of the drop and can describe the interaction between the liquid and the material surface. A contact angle higher than 90° indicates that wetting of the surface is not preferred. In this case, the liquid remains on the surface without spreading. On the contrary, when the contact angle is smaller than 90° , the wetting is favored and the liquid can spread on the surface. The terms hydrophobic and hydrophilic are used when water is used as liquid. Typically, in the scientific community, the definition is that a surface is hydrophilic when its static water contact angle is smaller than 90° and hydrophobic when the angle is more than 90° (Fig. 3).

Some surfaces can be qualified as superhydrophobic or superhydrophilic, if they exhibit water contact angles higher than 145° or lower than 10° , respectively. Water droplets immediately roll on the superhydrophobic surfaces while water simply lies as a flat film on superhydrophilic surfaces (Law, 2014; Otitoju *et al.*, 2017).

The wettability is a key factor in the cell adhesion and protein adsorption on a biomaterial surface. Indeed, some studies claim that enhancing the hydrophilicity of a surface can improve its interactions with the biological species especially for wound healing and osseointegration. Some improvements in the bone implant contact have been made with hydrophilic surfaces and osteoblasts cells exhibiting higher level of differentiation markers on these surfaces (Soon *et al.*, 2016). Moreover, it has also been proved that cells requiring substratum adhesion for proliferation prefer hydrophilic surfaces with water contact angle less than 60° . Therefore, the improvement of the attachment, proliferation and differentiation of cells like osteoblasts on a biomaterial surfaces is possible by increasing its hydrophilicity (Wu *et al.*, 2015).

Surface Topography

Surface topography is defined by surface orientation and roughness and is characterized by a succession of peaks and valleys (Goriainov *et al.*, 2014). Like wettability, surface topography has a real impact on cells adhesion, proliferation and differentiation on a surface. Indeed, there is a phenomenon called surface guidance that allows shaping cell morphology by changing the physical environment, especially the surface topography (Goriainov *et al.*, 2014). Roughness, which is the measure of the finely spaced micro-irregularities on the surface texture, is commonly used to quantify the topography (Choudhury and Chinchani, 2016). Roughness values can be obtained by several methods like Atomic Force Microscopy (AFM), Confocal Laser Scanning Microscopy, scanning interferometry or scatterometry. Although, it is delicate to compare roughness values obtained from different techniques because surface roughness changes as a function of scanning scale (Gong *et al.*, 2018). Distinct roughness levels can be observed depending on the average height deviation, S_a , which expresses, as an absolute value, the difference in height of each point compared to the average of the surface, according to ISO 25178-1:2016 (Geometrical product specifications – Surface texture: Areal – Part 1: Indication of surface texture). Typically, in the study reported by Goriainov *et al.* (2014), rough surfaces is defined as the average height deviation is higher than $2\text{ }\mu\text{m}$, moderately rough surfaces when S_a is between $1\text{--}2\text{ }\mu\text{m}$, minimally rough surfaces

when Sa is between 0.5–1 μm and smooth surfaces when the value is lower than 0.5 μm . Among these roughness levels, moderate surface roughness seems to be an optimal range to promote the biological integration of an implant. Indeed, moderately rough surfaces have been associated experimentally with stronger bone responses in vitro and in vivo besides with a better cell attachment. Excessively rough surfaces are characterized by very long distances between their peaks and so cells can perceive them as flat. The consequence is that flat surfaces can cause excessive cells flattening and then compromise their nutrition. Therefore, specific topographical modifications can be introduced to modify the roughness of a biomaterial surface in order to improve its interactions with cells and the biological environment.

Surface Chemistry

There is no doubt there is a strong dependence of cell adhesion and proliferation on substrate surface chemistry. Indeed, studies over the years showed that the surface chemical composition is primordial for protein adsorption and subsequent cell adhesion. The chemical structure on the surface can also guide cells fate and affect their shape (Liu *et al.*, 2007). Some particular surface functional groups like hydroxyl or carboxyl can particularly stimulate adhesion and proliferation of cells. Calcium phosphates are well known for their interaction with bone through protein adsorption and their ability to enhance cell attachment, spreading and osteoblast differentiation with some chemical surface impregnation like Mg, S, P, Sr, F and Ca (Goraiainov *et al.*, 2014). As well as

the chemical composition, particle size and crystallinity can also affect interactions between biomaterial surfaces and the biological environment. Generally, the smaller the particles sizes, the higher the total surface area and then the greater number of available binding sites for biomolecules interaction (Lee *et al.*, 2014). About the crystallinity, materials with lower crystallinity have higher solubility so the ionic strength can be increased in the surrounding medium. Biomolecules undergo structural conformational changes in high ionic strength media exposing more polar ionized charges on the surface. This phenomenon promotes a higher adsorption rate on the biomaterial surfaces with low crystallinity (Lee *et al.*, 2014). Therefore, chemical composition has an important role to play on the improvement of biomaterials biological interactions. It is possible to enhance surface behavior by some chemical modifications like coating, substitution, functionalization or incorporation. These different chemical treatments are discussed in detail in a next section. Nevertheless, it is a challenge in some cases to clearly separate cause and effect in the cell-adhesion/proliferation process of surface chemistry from all other surface properties. Indeed, most of surface properties are linked to each other. For example, surface wettability is a direct function of both surface chemical composition and surface topography (Liu *et al.*, 2007; Lee *et al.*, 2014).

Surface Modification Techniques

Even if surface properties discussed in the previous section are described for all types of biomaterials, this section is focused on surface modification techniques of bioceramics. Due to their properties (hardness, brittleness, great strength, stiffness, resistance to corrosion, resistance to wear and low density), ceramics surfaces need some special requirements to be treated (Patel and Gohil, 2012). Typically, surface modification techniques can be classified in two categories: physical and chemical modifications. On one hand, physical modifications provoke a change in the topography or morphology of the surface with no theoretical change of the chemistry of the surface. Techniques like machining, grinding, sandblasting, etching, polishing or laser texturing can produce such physical modifications. On the other hand, chemical treatments change the chemistry of the surface to enhance surface properties by UV light treatment, coatings, biofunctionalization or self-assembly (Bose *et al.*, 2018). Sections below describe the main physical and chemical surface modification techniques for biomaterials with the focus on ceramics.

Physical Modifications

Machining and Grinding

Typically when a biomaterial surface did not undergo any subsequent finishing, it is just called a machined surface. Most of the time, bioceramic parts are manufactured to get the final desired shape and are subject to cleaning, decontamination, passivation and sterilization (Elias, 2011). The two main methods to manufacture ceramics are cutting and grinding. These mechanical processes remove unnecessary parts of a material by sinking the cutting edge of a tool into a workpiece. In cutting, machining is performed by a cutting tool that has a cutting edge of the desired shape (Ohnishi *et al.*, 2015). The conventional cutting methods include diamond saw blade cutting, abrasive wheel cutting, wire saw cutting and mechanical mounting but some modern techniques have been developed over the years to minimize cracks and damages. Among these new techniques, there are wire electrical discharge machining, laser beam machining, abrasive water jet machining and hybrid machining (Rakshit and Das, 2019) (Fig. 4).

On the other hand, grinding is performed by large numbers of abrasive grains scattered on the outer surface of the grinding wheel. Many abrasives are suitable for the wheel surface but the physical properties of diamond make it an excellent candidate for ceramics grinding. Grinding can produce high shape accuracy, dimensional precision and can be used to create an appropriate roughness on a material surface (Ohnishi *et al.*, 2015).

Due to the extreme properties of ceramics, it is often a challenge to machine them. Indeed, ceramics are more susceptible to fracture during manufacturing processes because of their high hardness and brittleness. The surface can be highly influenced by the action and the types of cutting or the grinding tools. In most cases, machined surfaces present unwanted patterns of grooves from the manufacturing process, likely to influence in an uncontrolled way the interactions between the material and the biological medium (Fig. 5). Therefore, a finishing step usually follows the ceramics machining to optimize surface properties (Elias, 2011).

Sandblasting

Sandblasting or air-abrasion is one of the most common methods used for surface preparation. This technique has the advantage to create homogenous and anisotropic surfaces even on hard materials like ceramics or glasses. Indeed, it creates scratch-like irregularities using a high-speed stream of solid particles propelled by compressed air to remove unfavorable contaminants, increase surface energy, bonding surface area, and surface roughness (Fig. 6).

Alumina particles are usually used for their low cost, hardness, and needle-like shape but fractures can happen sometimes due to its brittle behavior. It is possible to tailor the obtained topography by varying parameters such particle size, particle shape, kinetic energy, pressure or impact angle. Moreover, the solid particles have to be clean as well as uniform-sized for the preparation of proper surfaces and the choice of the different parameters must avoid excessive damage to the material surface (Ebnesajjad, 2014; Soon *et al.*, 2016; Papageorgiou and Pandis, 2017).

It has been shown by Nothdurft *et al.* (2015) that a rougher surface obtained by sandblasting has favored the adhesion of fibroblast on zirconia. Nevertheless, the use of sandblasting can alter the surface chemistry by alumina contamination but this issue can be resolved by acid etching treatment. Indeed, this technique, discussed in the following section, can allow to remove surface residues (Soon *et al.*, 2016).

Chemical Etching

Chemical etching is a complementary surface modification technique to machining and sandblasting to its capability to induce a fine roughness sometimes up to the nanoscale. Most of the chemicals used for etching are acids like hydrofluoric acid, nitric acid or

Fig. 6 Scanning electron microscopic views of zirconia with three different surface topographies (machined, polished, and sandblasted) under 500 and 10,000 magnifications. Differential behavior of fibroblasts and epithelial cells on structured implant abutment materials: A comparison of materials and surface topographies. *Clinical Implant Dentistry and Related Research* 17, 1237–1249. doi:10.1111/cid.12253.

sulfuric acid. Nevertheless, some mixtures of potassium hydroxide and sodium hydroxide have also been used. Acid etching can produce some sharp edges on the treated surface (Fig. 7) but it can be smoothened by a following heat treatment.

The different parameters that influence the obtained topography are prior surface treatments, composition of acid mixture, temperature and treatment time (Fig. 8). Distinct types of topographies can be achieved by varying these parameters (Soon *et al.*, 2016; Flamant *et al.*, 2016).

This technique has some advantages like the obtaining of a homogeneous roughening of the material regardless its shape and size. Moreover, it can limit the risk of material delamination due to its absence of applied stress. On the other hand, some chemical changes can be induced by the presence of acids. These changes can modify the interactions between the ceramic material surface and the biological environment (Soon *et al.*, 2016). Some studies have investigated the effect of chemical etching on cells behavior. For example, Depprich *et al.* (2008) have shown that primary bovine osteoblasts are able to attach, proliferate and differentiate on acid-etched zirconia surfaces. Moreover, Ito *et al.* (2013) showed that the combination of sandblasting and acid etching can lead to an increase in the proliferation rate of osteoblast-like cells.

Polishing

Contrary to sandblasting and etching that create some surface roughness, polishing allows producing mirror-like surface with fine particle abrasives and soft pads. Indeed, it occurs by the sliding frictions between particles and the treated surface. Typically, the polisher travels across the work surface against which particles of abrasives are forced to the point of contact (Kasai, 2003). Silicon carbide polishing paper and diamond or silica suspensions are often used with a polishing machine to polish ceramic surfaces (Soon *et al.*, 2016).

Osteoblast cells are known to show good adhesion and proliferation on rough surfaces, but opposite behavior can be observed with other types of cells. For example, epithelial cells are known to attach better to a smoother/polished surface than to a rough surface. In addition to its ability to produce a very smooth surface, polishing can also serve to clean the implant surface. Indeed, mechanical treatment like polishing can theoretically clean without altering material chemical and physical properties. Nevertheless, there are always some surface modifications and contaminations due to abrasive suspensions used in the process (Soon *et al.*, 2016). Usually, polishing is applied as a surface preparation stage to obtain reproducible smooth surfaces before further treatment (Lasgorceix *et al.*, 2018).

Laser Treatment

Laser treatment of biomaterials has been widely studied over the past few years to improve surface properties and to investigate the effect of the surface patterning on cells behavior (Jeong *et al.*, 2011; Liang *et al.*, 2012; Shukla *et al.*, 2016). For ceramics, some studies show that the changes induced by laser treatments on different materials improve the wettability compared to untreated material (Lasgorceix *et al.*, 2018). In some cases, it has been observed a modification of the cellular response on laser treated surfaces, in particular cell guidance phenomena (Fig. 9).

Light amplification by stimulated emission of radiation (LASER) is a source of coherent electromagnetic radiation that can be applied to modify the surface of various materials from ceramics to metals and polymers. Due to the high power density generated, laser sources can melt, heat, create patterns and grooves or chemically modify the material surface. Depending on the laser parameters and the target material, laser treatments effects can affect only the surface or have also an effect deeper in the material. This last characteristic is interesting because it is possible to change surface properties without any effect on bulk ones. The major advantages of laser treatments are the rapidity and the absence of contact between the material and the laser that avoids any risk of surface contamination (Kurella and Dahotre, 2005; Soon *et al.*, 2016). About the treatment of ceramics, depending on the laser process parameters, it can cause only texturing of the surface to change the topography or it can involve modification of microstructure, grain refinement, phase transformations, mixing of multiple materials, and formation of composites on the surface (Kurella and Dahotre, 2005). Indeed, Samant *et al.* (2008) showed that repetition rate, scanning speed and pulse width of the laser can influence the interdendritic porosity and grain size of treated alumina. In the case of laser texturing, it is possible to create some complex periodic surface structures that can enhance properties involved in biocompatibility like protein adsorption and cell/surface interactions. Indeed, the use of a laser has the potential to produce uniform 3D micrometer and submicrometer structures with high resolution. Therefore, laser treatment of biomaterials can become a strong alternative to conventional

photolithographic processes in biomedical surface engineering (Kurella and Dahotre, 2005; Shukla *et al.*, 2016). The interaction between a laser beam and a solid ceramic material is quite complex and is still under investigation. Indeed, there are a large number of laser–matter interaction parameters such as laser pulse duration, wavelength, angular divergence, spot size and energy, physical properties of solid matter, surrounding environment composition, and pressure (Semerok *et al.*, 2002). Of course, different kinds of lasers are available to vary the processing parameters depending of the treated material. For texturing applications, CO₂, Nd: YAG, Ti: sapphire and UV lasers (excimers) are reported to be used for biomaterials. Moreover, it has been proved that femtosecond lasers have advantages over nanosecond and picosecond lasers for the treatment of biomaterials due to their higher precision, a reduced heat-affected zone and smaller amount of debris around the treated spot (Vorobyev and Guo, 2009). Indeed, it is preferable to limit the heat produced by the laser to treat thermal sensitive materials. Even if the benefits of laser-induced periodic surface structures on surface properties are becoming more evident throughout the scientific community, very few works have been conducted on surface structuring of ceramics in relation to its applicability in the biomedical sector. Therefore, laser surface structuring of bioceramics need further studies to understand fully the effects of nanosecond, picosecond and femtosecond lasers on the biocompatibility of treated ceramics (Semerok *et al.*, 2002; Kurella and Dahotre, 2005; Shukla *et al.*, 2016).

Other Techniques

Physical surface modification techniques cited above are the most currently used for ceramics. Indeed, this list is not exhaustive and more and more innovative techniques are being developed to optimize surface properties of biomaterials. Some examples are electron beam texturing, photolithography, ion beam texturing or electric arc texturing. Nevertheless, these methods present some limitations. Electron and ion beam processing need to be processed in vacuum chambers which means shape and size limitations for samples. Moreover, the use of these two techniques is expensive. Photolithography, on the other hand, is an extremely time-consuming multistage process compared to methods like laser treatments (Kurella and Dahotre, 2005).

Chemical Modifications

Ultraviolet Light Treatment

UV light treatment has been proven to enhance integration of bone implants due to this influence on the hydrophilicity. Indeed, the effect of UV light on titanium surfaces has been shown to improve their bioactivity and osteoconductive ability. This is possible by an increase of protein adsorption together with an osteogenic cell attachment and proliferation. This phenomenon is called “UV light-mediated photofunctionalization” and is associated with the photochemical and photocatalytic removal of hydrocarbons onto the material treated surface (Aita *et al.*, 2009). Same observations can be made for ceramics since Tuna *et al.* (2015) have shown that UV treatment of zirconia induced profound alterations in the surface physicochemical properties. Indeed, UV treated surfaces were converted from hydrophobic to hydrophilic status and a significant decrease in surface carbon content was observed. Similar results were also found by Att *et al.* (2009) with UV light treated zirconia disks. A treatment of 48 h substantially increased their capacity for attachment, spread, and proliferation of rat bone marrow-derived osteoblasts. The increased osteoblasts affinity for the UV-treated zirconia surfaces was already distinguishable within the first hours of seeding (Fig. 10).

Nevertheless, mechanisms involved in the modification of zirconia surface properties during UV treatment are not yet fully understood. Moreover, there is a need for further studies to determine the impact of these alterations on the surface biocompatibility (Tuna *et al.*, 2015; Soon *et al.*, 2016). Finally, this kind of UV treatment is mostly studied with zirconia ceramics and it could be interesting to investigate this surface modification technique with other bioceramics.

Coating

Coating of implant is one of the strategies used to enhance biocompatibility and osseointegration without changing the bulk material. Indeed, biomaterial coatings can be really useful to inhibiting bacterial colonization and to enhancing the attachment of tissue cells on the surface (Soon *et al.*, 2016). Coating technique consists in the covering of a surface with the same material or with a bioactive material (Chevalier *et al.*, 2011). In the case of a coating of the same material, it is usually realized to incorporate some porosity on the surface in order to promote osseointegration or even to allow bone in-growth (Fig. 11). To achieve a porous surface, the bioceramic implants are coated with slurry containing ceramic powder, like zirconia or calcium phosphate, and a pore-former. Sintering of the implants is performed to fully densify after the application of the coating. During this step, the pore-former burns off and leaves a porous surface. However, this way is sometimes complex in case of difficult control of the processing that can lead to poor mechanical properties and ageing resistance (Sennerby *et al.*, 2005; Chevalier *et al.*, 2011).

Besides, coating with bioactive ceramics is widely used to improve surface properties of metals like titanium or other inert ceramics. Calcium phosphates (CaP) are the best candidate for coating material due to their good biocompatibility, osseointegration and osteoconduction. The presence of a bioactive CaP coating can help to establish a stable interface between the implant and the bone besides with blocking the diffusion of toxic elements from the bulk implant into the body. Moreover, it can reduce the friction coefficient between the implant and its biological surroundings and enhance bone growth around the graft. Many

Low-temperature degradation in zirconia with a porous surface. *Acta Biomaterialia* (7), 2986–2993. doi:[10.1016/j.actbio.2011.03.006](https://doi.org/10.1016/j.actbio.2011.03.006).

processes exist to prepare synthetic CaP coatings such as plasma spraying, high-velocity oxygen-fuel, thermal spraying, sputter coating, radio-frequency magnetron sputtering, pulsed laser deposition, ion-beam deposition, frit enameling, hot isostatic pressing, metallic-organic chemical vapor deposition and electrodeposition (Eliaz and Metoki, 2017). Among these processes, plasma spray is currently the most common technique used commercially for coating implants with CaP, due to its versatility. This technique provides a high deposition rate and low cost. In this process, a high-frequency arc is ignited between an anode and a tungsten cathode. The gas flowing through between the electrodes is ionized and a plasma plume is developed. The spray material is injected as a powder outside of the gun nozzle into the plasma plume. There, it is melted and hurled by the gas onto the substrate surface. The molten and semi-molten particles rapidly solidify on impact against the substrate, and an integral layer is built-up by the overlaying of many particles. The relatively high temperatures involved in this kind of processes present some drawbacks like CaP phase transformation as well as the difference of thermal expansion coefficients between the bulk and the coating materials. Therefore, coatings present sometimes a lack of adherence to the substrate and process residual stresses may provoke delamination.

To avoid the problems related to high temperatures, the sol-gel process can be used and it is the simplest technique to manufacture thin films less than 1 µm. Indeed, it can be carried out at room temperature, and therefore, high temperature complications can be spared. Sol-gel coating can produce various materials with special functions and involves the formation of solid materials from solution. This is mainly inorganic compounds mixed in solutions of monomeric, oligomeric, polymeric or colloidal precursors. There are typically five stages during the sol-gel process. The first one is the production of a homogenous solution of the sol-gel precursors. Second, the addition of a suitable reagent, like water, is necessary to form a sol. The third step

consists in changing the sol to gel by poly-condensation. After, the gel can be shaped to get the final preferred shape such as thin films or fibers. The last step is the sintering of the shaped gel to obtain the desired ceramic material. This method has some advantages like an excellent adhesion, a good corrosion resistance, high purity material production, low sintering temperatures, process simplicity and the ability to coat complex shapes. Nevertheless, these advantages do not come alone. Indeed, the sol-gel process presents a high permeability, a low wear-resistance and a difficult porosity control. Moreover, the cost of raw materials is quite high that limits its industrial utilization (Eliaz and Metoki, 2017).

The choice of coating process is important but the surface preparation is crucial for the CaP coating properties. Indeed, a pre-treatment of a metallic or ceramic implant before coating with CaP allows to increase the adhesion strength, to control the corrosion rate, to increase nucleation kinetics, to control the structure, the porosity and the morphology of the coating, to improve the bioactivity and osseointegration of the coating, etc. Moreover, surface pre-treatments can also affect performance and longevity of the implant. Thus, different practices exist with their own advantages. Among the used surface pre-treatments, there are for example mechanical grinding, chemical etching, grit blast, soaking with NaOH or heat treatment (Eliaz and Metoki, 2017).

Post-treatments after coating are also widely applied to optimize coating properties. Most of the time, it is necessary to convert CaP phases with lower Ca/P ratio to hydroxyapatite or other calcium phosphate with a higher Ca/P ratio. Contrary to preparation methods, only two post-treatments are used commercially: sintering and soaking in an alkaline solution. The two methods can take several hours and produce different surface morphologies. Indeed, the sintering post-treatment generates preferably flake-like morphology compared to chrysanthemum-like structures obtained with the alkaline post-treatment. It has been shown that the crystallinity is increased by these two post-treatments but even more with sintering (Eliaz and Metoki, 2017).

Coating of materials is an interesting way to optimize implant surface properties in order to guide the integration of the graft. Calcium phosphate coatings can help for bone-implant bonding. Nevertheless, several flaws like variation in coating/implant bond strength can cause a poor coating stability and adhesion to the substrate. New techniques for depositing CaP-based coating on medical implants are constantly being developed to solve these different issues and to minimize the possibility of failure and delamination. Finally, it is well known that CaP based coatings with a higher dissolution rate enhance osteoblast response but their fast dissolution limits their stability. Therefore, there is also some progress to make with CaP coating materials (Soon *et al.*, 2016; Eliaz and Metoki, 2017).

Biofunctionalization

Compare to CaP coatings, biofunctionalization or biomimetic surface modification consists in the immobilization of biomolecules like proteins, enzymes and peptides onto the implant surface. This organic anchorage can alter the biochemical properties and the biological responses of the surface and the attached molecules. Indeed, the immobilization of charged biomolecules like proteins onto biomaterials can be oriented in a manner that is optimal for binding to their respective biological charged sites. With biofunctionalization, lots of drugs or proteins could be fixed onto the surface of biomaterials and minimize some biointegration drawbacks. Typically, there are three main kinds of biomimetic surface modification: direct or physical immobilization, chemical immobilization and bioaffinity immobilization (Lee *et al.*, 2014; Soon *et al.*, 2016).

The simplest way to impregnate biomolecules onto a ceramic surface (e.g., a CaP surface) is the direct immobilization or physical immobilization (Fig. 12). Proteins are adsorbed via weak non-covalent interactions like electrostatic, van der Waals, hydrogen bonding, and/or hydrophobic interactions. It is possible to modulate the environmental conditions around the material to regulate its capacity for protein adsorption. Physical immobilization allows some advantages such as the structural preservation of protein molecules and its applicability to most types of native surfaces. However, the binding affinities of proteins are usually quite low because of the non-specific character nature of this physical immobilization. Moreover, the blockage of binding sites and non-specific interaction of proteins with their surroundings can cause low adsorption or loss of protein activity (Lee *et al.*, 2014).

On the other hand, chemical immobilization approach consists of modifying the surface energy, charge, and composition of a material to attach proteins through covalent bonds (Fig. 12). Different methods are available for this achievement like covalent immobilization of organic functional groups, ion-bombardment, sol-gel, and treatment with acid/alkaline. Some examples of linkers that can bind proteins onto the surface of CaP are silanes, mercaptans and catechol. These linkers are able to connect with the side chain functional groups of proteins like amines, carboxylates, thiols or hydroxyls. Even if this kind of biofunctionalization allows strong links, this could be a drawback and a limit for the release of the attached proteins. Moreover, it is not a selective technique due to the presence of many functional groups on proteins (Lee *et al.*, 2014).

The last way to carry out biofunctionalization is called bioaffinity immobilization. This consists of the immobilization of a biomolecule via bioaffinity interactions with other biomolecules. In most cases, such bioaffinity immobilization is not wanted because it can lead to the biomolecule inactivation. Indeed, active sites can be blocked with this kind of interaction and cause the inactivation. Nevertheless, bioaffinity immobilization of biomolecules onto a ceramic substrate can also improve the biological activity (Lee *et al.*, 2014). The most famous example is the arginine-glycine-aspartate (RGD) which is a widely used adhesive peptide. Actually, many adhesive proteins are found to possess RGD as their cell recognition site (Soon *et al.*, 2016). In recent studies, RGD-peptide has been successfully immobilized on zirconia and hydroxyapatite surfaces and enhanced the biocompatibility of the material. Methods like hydrothermal treatment and silanization are used to optimize this immobilization (Lee *et al.*, 2014; Soon *et al.*, 2016).

Fig. 12 Types of surface modification processes commonly used for modifying CaP particles to achieve optimal protein or drug adsorption and cells–CaP interactions. Reproduced from Lee, W.H., Loo, C.Y., Rohanizadeh, R., 2014. A review of chemical surface modification of bioceramics: Effects on protein adsorption and cellular response. *Colloids and Surfaces B: Biointerfaces* 122, 823–834. doi:10.1016/j.colsurfb.2014.07.029.

Fig. 13 Scanning electron microscopy (SEM) image of self-ordered nanostructure on the (001) surface of YSZ. The inset fast Fourier transform of the SEM image shows evidence of the periodicity. Adapted from Rauscher, M.D., Andrew Boyne, A., Dregia, S.A., Akbar, S.A., 2008. Self-assembly of pseudoperiodic arrays of nanoislands on YSZ-(001). *Advanced Materials* 20 (9), 1699–1705. doi:10.1002/adma.200701383.

Self-Assembly

Another quite new technique for surface modification is self-assembly. This is defined as the autonomous process by which components organize into patterns or structures without external intervention (Whitesides and Grzybowski, 2002). Self-assembling processes involve components from the molecular to the planetary scale and many different kinds of interactions in both nature and technologies. This kind of techniques can be of great interest because it is one of few practical strategies for making nanostructures. Typically, two main kinds of self-assembly exist for the moment. On one hand, static self-assembly involves systems that are at global or local equilibrium. It does not dissipate energy contrary to dynamic self-assembly. In dynamic self-assembly, the formation of structures or patterns takes place with interactions that only occur if the system is dissipating energy (Whitesides and Grzybowski, 2002).

Fig. 14 Scanning electron microscopy of nanofeatures manufactured using GDC/YSZ system: (a) islands, (b) connected islands, and (c) pits. Reproduced from Parikh, K.S., Rao, S.S., Ansari, H.M., *et al.*, 2012. Ceramic nanopatterned surfaces to explore the effects of nanotopography on cell attachment. *Materials Science and Engineering C* 32 (8), 2469–2475. doi:10.1016/j.msec.2012.07.028.

Fig. 15 Schematic representation of the formation mechanism of Ca-P/polydopamine composite nanolayer on the surface of β -TCP ceramics. Reproduced from Wu, C., Han, P., Liu, X., *et al.*, 2014. Mussel-inspired bioceramics with self-assembled Ca-P/polydopamine composite nanolayer: Preparation, formation mechanism, improved cellular bioactivity and osteogenic differentiation of bone marrow stromal cells. *Acta Biomaterialia* 10 (1), 428–438. doi:10.1016/j.actbio.2013.10.013.

There are different examples of this process applied with ceramics such as CaP or zirconia. Rauscher *et al.* (2008) have succeeded in depositing a gadolinia-doped ceria (GDC) on yttrium stabilised zirconia with pseudoperiodic-array of nanoislands on the surface after thermal treatment (Fig. 13). Such nanopatterned surfaces (Fig. 14) were shown by Parikh *et al.* (2012) to exhibit satisfying cellular responses such as remarkable changes in cell spreading and cytoskeletal protein distribution.

About CaP, Wu *et al.* (2014) inspired themselves from mussels to prepare a uniform CaP/polydopamine composite nanolayer on the surface of β -tricalcium phosphate bioceramics by soaking β -TCP bioceramics in Tris-dopamine solution (Fig. 15). This formed self-assembled CaP/polydopamine composite nanolayer significantly enhances the surface roughness and hydrophilicity of β -TCP ceramics and stimulates the attachment, proliferation, alkaline phosphate activity and bone-related gene expression of human bone marrow stromal cells.

Surface Treatment Perspectives

Finally, as explained in this chapter, the major goal of bioceramic implants is their proper osteointegration into a bioenvironment. For that, it has been shown that the implant surface is determinant. Many surface modification techniques exist to optimize the implant integration. The future of surface modification techniques on ceramics is promising but a lot of work has still to be done. Indeed, there are many contradicting results in the scientific community and more comprehensive researches have to be carried out to uncover complex mechanisms behind surface properties and cellular response. Moreover, current surface modifications techniques have to be improved in order to produce optimized bioceramic surfaces. In that case, surface modification will be a way to improve the reliability of bioceramic implantation for humans.

Introduction

The reconstruction of bone defects, especially in the cases of large osseous defects, remains a significant clinical issue (Marchat *et al.*, 2013). These defects could result from trauma, malformations, cancer or other pathologies such as osteomyelitis or osteoporosis, and the current approaches, including autografts, allografts or synthetic biomaterials, are not satisfactory. In the field of bone substitution, bone autograft is considered as the gold standard because it contains the extracellular matrix (ECM), growth factors and osteocompetent cells, which are essential to support the induction and growing of new bone (Giannoudis *et al.*, 2007, 2008). Nevertheless, their use is limited by the narrow amount of bones able to be autografted, their shape and their size that cannot always be adapted to the defect geometry, and by an excessive graft resorption. Furthermore, the bone samplings induce pain, infections, hemorrhages and an increase of morbidity. While allografts may avoid the mentioned drawbacks, they are inclined towards transmitting infectious diseases that also limit their use (Hinsenkamp *et al.*, 2012). This is the reason why synthetic bone substitutes fulfilling a well-defined function and having, in some cases, strong interactions with host tissues have been developed.

The first generation of biomaterials (*i.e.*, bioinert materials) appeared in the 1960s and followed the advances in medicine and biomechanics. Their interaction with the living tissues is limited to the formation of a very thin fibrous layer of encapsulation, and they remain chemically stable even after several years of implantation. The improvement of biointegration has led to a second generation of bioactive and/or biodegradable biomaterials. Bioactive materials are bound to the host tissues and interact positively with it, and biodegradable materials are replaced by living tissue after a few weeks or months of implantation (Hench and Polak, 2002). Due to a chemical composition close to the bone mineral calcium phosphates, such as hydroxyapatite (HA, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) or beta-tricalcium phosphate (β -TCP, $\text{Ca}_3(\text{PO}_4)_2$), are classified among them and they are used since the early 1980s (Jarcho, 1981). This chemico-physical analogy with bone gives to porous calcium phosphate based bioceramics (CPC) specific properties. When shaped to the form of scaffolds or granules, they are highly biocompatible and osteoconductive as they allow the adhesion, the proliferation and the differentiation of cells on their surface (Elliott, 1994). CPC may indeed have two types of porosity: a micro-porosity (pore diameters less than 10 μm), which is involved in the phenomena of exchanges with biological fluids, and a macro-porosity (pore diameters from a few tens to a few hundred micrometers), which is a determining factor for vascular invasion and cellular colonization of substrates (Burg *et al.*, 2000). The new bone tissue grows from the host bone and penetrates within the interconnected macro-pore network of scaffolds or within the interstitial voids; the resorption of substitutes will be then driven by their chemical composition. However, osteoconduction phenomenon is limited, this bone ingrowth only occurs up to about 1 cm from the bone apposition (Petite *et al.*, 2000). While they are osteoconductive, CPC are not or weakly osteoinductive (Bose and Tarafder, 2012); therefore full-bone repair is restricted to defects of small dimensions. As a result, since the early 2000s, research has been focused on the development of the third generation of bioceramics, which are able to interact strongly with the host bone tissues. The interactions between biomaterials and living tissues are crucial from the adhesion of progenitor cells to their differentiation into mature actors of bone healing. The current conception of what the ideal bone biomaterial should be and what biological properties it should have taken into account this integrated vision of the physiology of the bone repair (Vishwakarma *et al.*, 2016; Lopes *et al.*, 2018). Ideal bone substitutes have to stimulate the bone repair through the induction of bone cell differentiation (osteoinductive materials), which is mandatory and needs the existence of an efficient vascularization. They also have to be embedded into the natural bone to insure the mechanical and functional integrity of the bone structure, *i.e.*, to have osteointegrative properties (Chen *et al.*, 2016).

Among the biomolecules employed for biomaterial surface functionalization, we will focus on the biomimetic approach employing molecules that are produced by cells or their synthetic derivatives. Then we will present the different routes of functionalization of CPC with a focus on the covalent immobilization based on the use of anchors, cross-linkers and specific chemical reactions. Finally, we will expose the main *in vitro* and *in vivo* experiments performed to evaluate the added-value of CPC functionalization.

Molecules to Stimulate Biological Events

The biological events occurring during the bone repair and following a bone substitute implantation consist of coordinated and sequential processes involving cellular actors from three distinct physiological systems: immune, vascular and skeletal (Fig. 1). So, the molecules being tethered to biomaterial surfaces are intended first to target mainly monocytes and macrophages for the osteoimmunomodulatory (OIM) strategies. The second target is the osteogenic cells and functional osteoblasts originated from the differentiation of mesenchymal stem cells (MSC). All these cells are directly addressed by adhesive, proliferative and/or osteogenic

Fig. 1 Schematic representation of strategies and natural molecules used to chemically functionalize CPC. (1) The first event to occur after material implantation is the adsorption of extracellular matrix (ECM) proteins, which allow cell adhesion. In order to mimicry this event, molecules that can be tethered with biomaterials are ECM-related molecules *i.e.*, (a) full-length proteins or (b) short peptides. Another category of natural molecules used is growth factors (GF) and cytokines (CK) that can trigger either (2) specific progenitor differentiation into mature bone (osteogenesis) or endothelial cells (angiogenesis and vascularization) or (3) osteoimmunomodulation that consists of activating macrophages, effector cells of the innate immune response, in order they secrete communicating molecules able to stimulate processes involved in bone repair.

molecules. In addition, stimulation of endothelial cell activities will allow to theoretically improving the biomaterial vascularization. The proteins that belong to the extracellular matrix are essential players (Hankenson *et al.*, 2015) in the initiation of the coordinated biological events leading to bone rehabilitation. The coordination of the associated cells activities, whatever their type and the physiological system to which they belong, lies on the secretion of extracellular signaling molecules. They are mainly growth factors (GF) and cytokines (CK) and they could be pharmacologically triggered (Hankenson *et al.*, 2015). GF and CK are freely released by cells, but can also be trapped into the ECM meshwork by interaction with resident proteins (*e.g.*, fibronectine, heparin) and released during the ECM remodeling. Different strategies can be followed to stimulate either of these systems.

Adhesive Proteins From ECM and Derivatives: Enhancement of Cell Adhesion, Proliferation and Activities

The first event to occur just after a biomaterial implantation, and before interaction with cells is the absorption of ECM proteins from interstitial liquid and blood ((1) in Fig. 1) (Wilson *et al.*, 2005). Then ECM proteins elicit the cell attachment, adhesion and spreading (Chen *et al.*, 2018). The cell function, phenotype and physiological activities will be modulated depending on the cell nature. The selective adhesion of cells to such proteins is mainly performed through the integrins. They are transmembrane heterodimeric receptors, constituted by the assembly of one α and one β subunits (18 and 8 isoforms exist for each subunit type, respectively). This leads to one of the 24 known combinations with differential affinities toward the ECM proteins (their ligands) that are distributed regarding to the cell types. These combinations are associated with the regulation of specific cell functions (cytoskeleton remodeling, cell survival, proliferation or differentiation) through interactions with the intracellular molecular regulators (Marie *et al.*, 2014; Kechagia *et al.*, 2019). To improve osteointegrative properties of biomaterials, standard strategies take advantage of the adhesive properties of bone ECM proteins (osteopontin, bone sialoprotein, fibronectine, type I collagen, vitronectin, *etc.*) to enhance cell adhesion and further cellular activities (Shekaran and Garca, 2010; Chen *et al.*, 2018). The following section presents references corresponding to reviews or examples of works using these strategies but it is far to be exhaustive.

Biomaterials can be functionalized with full ECM adhesive proteins such as fibronectin (Fn) (Kawashita *et al.*, 2016) or type I collagen (Hennessy *et al.*, 2009). Whereas most of the cells are sensitive to Fn or collagens, functionalization with other ECM adhesive molecules like laminin is more common to increase adhesion of endothelial and/or neural cells. The majority of investigations carrying out this functionalization strategy are based on the use of synthetic short RGD (Arg-Gly-Asp) peptides, discussed recently in Huettner *et al.* (2018). The RGD motif, identified in Fn by Pierschbacher and Ruoslahti (1984), is shared by numerous ECM proteins and is the shortest active amino acid (aa) sequence recognized by their associated integrin receptors. Short aa sequence is easily synthesized and less immunogen than full length proteins. This is why tethering of RGD to biomaterial surface by absorption or covalent immobilization is widely used in the literature (for example Durrieu *et al.* (2004)). In full-length proteins, aa flanking the RGD motif modulates the strength of its recognition by each integrin complex subtype. This consequently alters the attachment and the subsequent behavior of cells. Modifications of the RGD motif by adding other aa were done to obtain more specific cell responses by triggering specific $\alpha\beta$ integrin heterodimers (see Huettner *et al.* (2018) for a review). The cell responses will be modulated by the density of molecular tethering and by the kind of stimulated integrins (Perlin *et al.*, 2008; Chollet *et al.*, 2009) and also by the density of full length ECM proteins such as the Fn (Matsui *et al.*, 2015).

While RGD and its derivatives are the preferential choices for functionalizing biomaterials with adhesive peptides, other short aa adhesive sequences may be used (Wang *et al.*, 2017). Fn functional domains derivatives such as type II Fn domains (Pereira *et al.*, 2017) or the ninth type III Fn domain PHRSN may be employed (Redick *et al.*, 2000). The impact of this latter short aa sequence on cell adhesion was evaluated on many polymers and titanium substrates while being often co-attached with an RGD motif for a stronger cell response (Chen *et al.*, 2013; Pramono *et al.*, 2016; Aye *et al.*, 2018). Surface functionalization with a DGEA motif, derived from collagen, can enhance the differentiation process of osteogenic progenitors (Mehta *et al.*, 2015). YIGSRD and IKVAV, respectively derived from laminin and elastin, are also considered, alone or in combination with other sequences to improve their efficiency, especially by enhancing the adhesion of endothelial, muscular or neural cells (dos Santos *et al.*, 2019; Peng *et al.*, 2019). Another way to enhance osteoblast adhesion has been to conjugate KRSR, a peptide mimicking the proteoglycan domains recognized by heparin, to nanocrystalline hydroxyapatite (Nelson *et al.*, 2006). A recent new kind of modified mimetic peptides called elastin-like recombinamers was designed to combine the advantages of adhesive peptides with antifouling properties (Ciofani *et al.*, 2013). They were proven to have interesting biological properties in a context of bone regeneration both *in vivo* and *in vitro* (Tejeda-Montes *et al.*, 2014) but to our knowledge they have not been used yet to functionalize calcium phosphate based materials.

The choice of ECM protein mimetic peptide to enhance cell adhesion can be crucial since some are stimulating the exclusive adhesion of a specific cell type. The targeting of specific integrin receptors to trigger adhesion of a given cell type can be successfully achieved through screening procedures. Recently Kanie *et al.* have defined short active aa sequences from type IV collagen that differentially enhance the specific adhesion of endothelial or smooth muscle cells (Kanie *et al.*, 2012).

Growth Factors and Cytokines: Inducing Specific Cell Behaviors

GF and CK are signaling molecules produced by cells to regulate the behavior of targeted cells in the vicinity of the emitting cells (paracrine communication) that can be of the same cell type (autocrine signaling). Due to the specific chemotactic, proliferative or differentiating effects induced by these molecules, and their relatively small size, GF and CK constitute an attractive way for functionalization (Lee *et al.*, 2011; Tollemar *et al.*, 2016). Moreover, immobilization allows for a local administration with a limited diffusion and avoids supraphysiologic doses that may limit side effects associated to a broader delivery of GF (Hajimiri *et al.*, 2014). The potential efficacy and specificity of GF allow for the development of complex strategies to create smart biomaterials ((2) to (3) in Fig. 1). Indeed, in response to GF stimulation, receptor cells can in turn secrete other GF and CK, inducing further responses. The choice and the design of GF-functionalized biomaterials for bone tissue engineering are discussed in (Przekora, 2019).

Stimulating Bone Cells: Regulation of Osteogenic Differentiation

To make an osteoinductive material, the obvious strategy is to use molecules that are physiologically involved in the regulation of osteogenic differentiation. The GF molecules involved in osteogenesis that are likely to be used for material improvement are well known (Linkhart *et al.*, 1996; Lee *et al.*, 2011; Ripamonti *et al.*, 2006). The first inducible process is the homing of the osteogenic precursors MSC (Fiedler *et al.*, 2002) to the material surface (Andreas *et al.*, 2014). To this purpose, the linkage of a chemotactic GF such as the human PDGF-BB (platelet-derived growth factor-BB) (Phipps *et al.*, 2012) or the SDF-1 α (stromal derived factor 1 α – also known as CXCL12) allows the recruitment of MSC to the material surfaces (Shen *et al.*, 2016; Zhang *et al.*, 2018). To enhance efficiency, GF stimulating stem cell recruitment can be co-attached with osteogenic GF such as bone morphogenic proteins (BMP) (Ratanavaraporn *et al.*, 2011; Shen *et al.*, 2016), which are able to stimulate together both stem cell recruitment and the induction of osteogenesis (Lowery and Rosen, 2018). For example, SDF-1 α is able to modulate the effect of BMP-2 (Hosogane *et al.*, 2010). BMP are frequently employed, as illustrated by the extensive literature that may be found about their use. BMP2 has been the most widely chosen for this purpose (*e.g.*, (Damia *et al.*, 2019; Lin *et al.*, 2019a)). The use of BMP2 and BMP7/OP-1 (osteogenic protein 1) has indeed been approved by the FDA (Food & Drug administration) for the treatment of spinal fusion and bone defects (Hustedt and Blizzard, 2014; Mckie *et al.*, 2014). However, BMP2 was associated to serious adverse effects and medical concerns that limits its clinical use, which even led to an FDA warning in 2008 (James *et al.*, 2016). This point requires a profound reconsideration about how to use it (Bialy *et al.*, 2017). It has been demonstrated that the way a GF is linked to the material surface affect its biological effects (Suliman *et al.*, 2015). In this respect, K. Anselme *et al.* have compared the effects of three BMP (BMP2, BMP6 and BMP7) associated with a human Fn for the functionalization of TiHA surfaces (Brigaud *et al.*, 2017). Some mimetic shorter peptides have also been proven to be efficient on osteogenic cell activities *in vitro* (Zouani *et al.*, 2010). Their benefit lies in that they reproduce at least a part of BMP2, BMP7 or BMP9, known as “knuckle epitope” (Saito *et al.*, 2003), which corresponds to the ligand domain recognized by the BMPRII (BMP type II receptor). The shorter size of such peptides should enhance their effect and efficiency by limiting possibilities of misfolding or misorientation when anchored to the surfaces of materials (Zouani *et al.*, 2010).

Other osteogenic GF of interest for inducing osteogenic differentiation are the members of the FGF (fibroblast growth factor) family (Feito *et al.*, 2010; de la Concepción Matesanz *et al.*, 2012), IGF-1 (insulin-like growth factor 1) (Gao *et al.*, 2015), TGF- β (transforming growth factor β) (Gu *et al.*, 2016) and PDGF (platelet-derived growth factor) (Raghavendran *et al.*, 2016; Bateman *et al.*, 2005; Kämmerer *et al.*, 2016; Santana and Santana, 2015) that can be combined with BMP2 (Thoma *et al.*, 2016; Kim *et al.*, 2013).

Recently, some studies have focused on a short natural peptide present in the bone ECM that have similar properties as a GF, namely the OGP (osteogenic growth peptide) (Policastro and Becker, 2015; Moore *et al.*, 2010).

Stimulating Endothelial Cells: Pro-Angiogenic Growth Factors

Vascularization of biomaterials is an important concern that conditions the success of the bone repair (Hu and Olsen, 2016). Just as in the case of osteogenesis, angiogenesis, which is the formation of new blood vessels from existing ones, can be regulated by several GF and CK molecules (Bayer *et al.*, 2015). The GF the most employed for this purpose is the VEGF (vascular endothelial growth factor) (Hu and Olsen, 2016). Whereas the stimulation of vascularization by CK may be indirectly achieved through the stimulation of innate immune cells or osteogenic precursors, the direct approach consists in the functionalization (adsorption or covalent route) by GF directly acting on endothelial cells (García and García, 2015). Hence, by stimulating production of VEGF by osteogenic cells, BMP such as BMP2 and BMP4 can be considered as angiogenic growth factors in multicellular systems (Deckers *et al.*, 2002; Kuttappan *et al.*, 2018).

Osteoimmunomodulation: Stimulating Messenger Immune Cells to Control Bone Healing

A strong immune response is harmful to the patient and can lead to serious adverse events until complete failure of the implantation (Anderson *et al.*, 2008). However, the existence of a basal immune response is necessary and conditions the success of the subsequent tissue repair (Horwood, 2015). Osteoimmunomodulation (OIM) is based on the foreign body reaction (FBR) occurring after a bone substitute implantation. The FBR, is a natural event induced by the hematoma formation following the blood vessel injuries after the surgical intervention. Extravasated innate immune cells (monocytes, macrophages) are activated by ECM proteins adsorbed on the fibrin-rich blood clot and on the biomaterial surface, and adhere onto it (Lin *et al.*, 2019b). The essential role of immunity and macrophages in bone repair is known to be crucial (Horwood, 2015). Therefore, guided bone regeneration by OIM (detailed in (Sridharan *et al.*, 2015; Chen *et al.*, 2016; Julier *et al.*, 2017; Spiller *et al.*, 2015)) is a relevant strategy that has recently been described. By controlling the activation of immune cells (mainly macrophages) to trigger the adequate secretion of immune signaling molecules, this strategy aims to induce and accelerate bone repair. By creating a favorable micro-environment where osteogenic and endothelial progenitors can be recruited, OIM should favor their proliferation, promote or even efficiently induce their differentiation. Depending on the local molecular micro-environment, macrophages can be activated and oriented according to two distinct and complementary secretory profiles (phenotypes) called M1 and M2 (Murray, 2017). The pro-inflammatory and pro-angiogenic M1 polarization (*i.e.*, its phenotypic orientation) is an early process induced by pro-inflammatory molecules such as interferon- γ (IFN- γ) or pro-inflammatory interleukins (IL, *e.g.*, IL-8). CK and GF released by M1 macrophages (*e.g.*, IL-1 β , prostaglandin E2 or SDF-1 α) are able to recruit and stimulate MSC (Pajarinen *et al.*, 2019). Occurring later, the switch to M2 polarization, globally anti-inflammatory, pro-healing, and favoring matrix deposition and tissue remodeling, is essential for bone healing (Mantovani *et al.*, 2012; Vi *et al.*, 2015; Chen *et al.*, 2016; Vishwakarma *et al.*, 2016). It can be induced by exposing macrophages to interleukins such as IL-4, IL-10, which will secrete in turn TGF- β , PDGF-BB, VEGF, and IGF-1. Therefore the macrophage polarization may be induced by a functionalized material (Sridharan *et al.*, 2015). This field gains in interest, as demonstrated by the special issue of the review Biomaterial published in March 2019, edited by Goodman and Ouyang (2019). The main advantage is the amplification of the signal by the synergy of GF and CK products, triggering then both osteogenesis and angiogenesis. Somehow, this strategy will work as a potent “multi-functionalization”. But the biggest difficulty is to act finely in order not to induce an unfavorable immune reaction leading to chronic inflammation, which could range from the formation of a fibrous capsule to a chronic inflammatory reaction and finally to the biomaterial rejection (Anderson *et al.*, 2008). Some recent examples of osteoimmunomodulation triggering osteogenesis and angiogenesis to enhance osteointegration *in vitro* and *in vivo* can be found in the literature. A first category of studies consists in the functionalization, *i.e.*, the macrophages polarization, with a unique molecule such as IL-8 or IL-4 (Lin *et al.*, 2019a; Yin *et al.*, 2019). Interestingly, more complex system have been developed to tune M1-to-M2 macrophage polarization (Alvarez *et al.*, 2016; Spiller *et al.*, 2015). To this end, (Spiller *et al.*, 2015) have engineered decellularized bovine bones. Their strategy has been on one hand to adsorb IFN- γ in order to first activate the macrophages towards the M1 phenotype by a fast release (Li *et al.*, 2008). And on the other hand they have covalently attached IL-4 to have a slow release and an induction of the M2 phenotype afterwards. A similar strategy was followed by (Alhamdi *et al.*, 2019) and by Li *et al.* (2008).

Chemical Functionalization Routes of CPC

The aim of the chemical functionalization is to improve the biological behavior of CPC by the addition of biomolecules (*i.e.*, full-length proteins or short aa sequences). While the behavior of the biomolecules could be slightly modulated, the receptor-ligand interactions have to be preserved by the functionalization (Rahmany and Dyke, 2013) whatever the chemical functionalization routes is. The following section summarizes of the routes employed for CPC different chemical functionalization, but does not precise the one used for a define biomolecule.

Substrate/Protein Interactions

The chemical functionalization routes of CPC are commonly classified according to the resulting strength of the substrate/protein interactions. Adsorption corresponding to direct interactions between the targeted biomolecule and the substrates and covalent immobilization employing intermediate molecules have to be distinguished.

Functionalization by proteins is commonly carried out by immersing the calcium phosphate substrate into an aqueous solution leading to the absorption of the targeted molecule (Hennessey *et al.*, 2009; Kawashita *et al.*, 2016). The characterization of biomolecule adsorption on solid surfaces is well documented in Migliorini *et al.* (2018) and in Thyparambil *et al.* (2015). When occurring, the adsorption phenomenon is influenced by the experimental conditions used (pH, ionic strength, temperature, *etc.*) and the surface properties of the substrate. Protein adsorption typically increases with roughness, microporosity, charge surface, crystallinity and specific surface area of the substrates (Lee *et al.*, 2014). Generally, the bindings between the adsorbed molecules and the adsorbent are ensured by weak electrostatic interactions, *i.e.*, Van der Waals forces (Debye forces $< 1 \text{ kJ mol}^{-1}$, Keesom interactions $\sim 3 \text{ kJ mol}^{-1}$ and London dispersion forces in the $1\text{--}10 \text{ kJ mol}^{-1}$ range), or hydrogen bonds ($20\text{--}40 \text{ kJ/mol}$) (Fig. 2(a)). This physisorption, which could be modeled (for example (Capriotti *et al.*, 2007)) does not result in any alteration of the protein molecular structure, as no irreversible bond is formed and no change in the chemical functions of the molecule occurs. However it may induce an aggregation and a fibrillation of the protein (Pellenc *et al.*, 2006) or a modification, certainly reversible, of its secondary structure (Paul and Sharma, 2008; Iafisco *et al.*, 2010; Matsui *et al.*, 2015). Finally, physisorption generates mono – or a multi-layer adsorptions (Wang *et al.*, 2012) and leads to a fast and not well controlled release over time (Parent *et al.*, 2016). Nevertheless, it is possible to obtain a mono-layer of strongly adsorbed molecules. In this case, adsorption is accompanied by changes in the distribution of the electronic charges and of the adsorbed molecules leading to ionic bonds (Roussière *et al.*, 2008). This is particularly the case of bisphosphonates (BP) that are able to chemisorb onto calcium phosphates. These stable analogous of pyrophosphate groups ($\text{P}_2\text{O}_7^{4-}$) are characterized by a P–C–P bond linking of two phosphonate groups and they are resistant to enzymatic hydrolysis. Their characteristic chemical structure allows them to get bound to the bone mineral and thus to influence the activity of the cells responsible for bone remodeling (their biological activity is related to their side chains), as illustrated by their use in osteoporosis treatments (Russell, 2007). Due to their affinity for calcium phosphates and the various ending functions of their side chains, the BP can be used as intermediate molecules (Fig. 2(b)) to modify the surface of CaP implants by biologically active molecules (Schuessele *et al.*, 2009; Yewle *et al.*, 2012) but the anchoring of BP requires reactive surfaces with large specific surface areas (Pascaud *et al.*, 2013) which is not the case of CPC for which the specific surface areas are much lower than $5 \text{ m}^2 \text{ g}^{-1}$.

In the case of the CPC, which need thermal treatment during the shaping process and which present low specific surface areas, the most relevant route is the “covalent immobilization” one. Based on the establishment of strong ionic-covalent bonds between the molecule of interest and the surface of the substrate, it may be carried out after their sintering. Chosen by several research teams, it is reported to offer advantages including the control of the surface density and the release kinetics of the bio-molecules.

Fig. 2 Drawing summarizing the different approaches for the functionalization of calcium phosphate bioceramics with: (a) physisorption, where the binding of biomolecules is ensured by low electrostatic interactions or hydrogen bonds, (b) chemisorption using bisphosphate molecules and (c) covalent immobilization using silanes. In these last two routes, bisphosphonates and silanes are utilized as anchors and require a reactive terminal function (*e.g.*, an amine) allowing the addition of the spacer and then the protein or peptide sequence.

Most of the protocols are based on approaches involving three steps: (1) the surface modification of the substrate surface using silane as anchor to provide reactive functions, (2) the addition of a bi-functional molecule (cross-linker) and finally (3) the immobilization of biomolecules (Fig. 2(c)). The control of the silanization step must make it possible to control the surface density of the biomolecule and therefore its biological activity.

Functionalization by “Covalent Immobilization”

Silanization

Silanization, developed by Plueddemann (1982), is frequently used to modify the surface of an inorganic substrate by providing a strong substrate/organic molecule bond. Silanization is a simple and inexpensive technique applicable to different types of materials: colloidal particles, porous materials, flat surfaces, polymer-reinforced composite materials. Firstly developed to modify the surface of metal oxides and glasses, it was then adapted to other types of substrates having hydroxyl surface groups. The silanes that are used for functionalization have a general formula of $R_nSiX_{(4-n)}$ where R refers to a non-hydrolyzable chain, X to a hydrolyzable group and the functionality term indicates the number of hydrolyzable X groups. A surface silanization reaction is a competition between the reactions resulting from the hydrolysis of the X groups: their homocondensation (or oligomerization) leading to the formation of oligomers and then to a 3D network and their heterocondensation onto surface hydroxyl groups of the substrates (Fig. 3). Their mechanisms are similar and mainly influenced by the pH, the nature of the solvent (aqueous or organic), the reaction time and temperature, the silane concentration and the nature of its carbon chains (functionality, length and functions) and finally the chemistry and the topography of the substrates (Howarter and Youngblood, 2006; Böhmeler et al., 2011; Siniscalco et al., 2019).

Since the beginning of 2000, the silanization is widely employed for the chemical modification of calcium phosphates to provide primary amine free functions for the subsequent immobilization of biomolecules like short aa sequences or full-length proteins. The amine-terminal functions will later react, *via* nucleophilic addition, with specific groups like aldehyde functions for example (see the subsection hereafter). Consequently, the density and distribution of the biomolecules will be directly determined by those of the anchor agent and the biological properties of the biomaterial will depend on the initial silanization. Thus, a good knowledge of this first step is of prime importance. While the reaction conditions have a strong influence on the silanization,

Fig. 3 Schematic representation of the water influence on the surface modification of an oxide surface by an silane (organotrimethoxysilane): (left) anhydrous conditions lead to heterocondensation whereas (middle) homocondensation, and then (right) 3D network, will result from an excess of water. Mutin, P., Guerrero, G., Vioux, A., 2003. Organic-inorganic hybrid materials based on organophosphorus coupling molecules: From metal phosphonates to surface modification of oxides. *Comptes Rendus Chimie* 6, 1153–1164. doi:10.1016/j.crci.2003. Copyright from Elsevier undergoing.

silane and substrates affect it also. The APTES (3-aminopropyltriethoxysilane) is the most employed silane for silanization of biomaterials (Durrieu *et al.*, 2004; Swan *et al.*, 2005; Zurlinden *et al.*, 2005; Balasundaram *et al.*, 2006; Nelson *et al.*, 2006; Wang *et al.*, 2008; Detsch *et al.*, 2009; Acharya *et al.*, 2012; Poli *et al.*, 2019; Damia *et al.*, 2019) but leads to polymerization. The impact of the R non-hydrolyzable chain can be assessed at the surface of model such as a silicone wafer. Böhmler *et al.* have shown that compared to APTES, the molecular assembly is better in the case of AHAPS (N-(6-aminoethyl)-aminopropyltrimethoxysilane) – which presents long and non-alkyl chains (Böhmler *et al.*, 2011). Nevertheless, the folding or reversal of the silane molecule significantly affects the accessibility of the amine-terminal groups and therefore the possibility of a subsequent binding of the biomolecules.

Most of the investigations have been devoted to prove the presence of the molecule on the ceramic surface and to determine the quantity of it. To access to the constituent elements, the organic modifiers and the chemical composition of the surface after functionalization, spectroscopic methods such as energy-dispersive spectroscopy, secondary ion mass spectrometry, infrared spectroscopy (FTIR) or attenuated total reflection Fourier transform infrared spectroscopy (ATR-FTIR) and X-ray photoelectron spectroscopy (XPS) are often used (Treccani *et al.*, 2013). Thermogravimetry analyzes (TGA) coupled with mass spectroscopy (MS) are employed for the study of the interaction strength between the attached organic groups and the surface and estimate the quantity of immobilized molecules (Damia *et al.*, 2019). In parallel, the spatial repartition and coverage of the ceramic surface by silane molecules can be investigated by Raman mapping. Recently, silanization of hydroxyapatite ceramics has been studied by Siniscalco *et al.* (2019). In a biological point of view, silicate substituted hydroxyapatite (SiHA, $\text{Ca}_{10}(\text{PO}_4)_{6-x}(\text{SiO}_4)_x(\text{OH})_{2-x}$) are of a great interest as silicon is known to influence the strength, the formation and the calcification of the bone tissue (Carlisle, 1970; Carlisle, 1972). In a chemical point of view, silicate groups can provide preferential sites on the ceramic surface *via* Si–O–Si covalent bonding between CPC and silane molecules (Ek *et al.*, 2003). The Raman maps (Fig. 4) show, whatever the silane and the substrates are, the presence of hillocks evidencing polymerization and/or aggregation of the molecules. But the spots are more intense on SiHA than on HA highlighting the substrate influence. The fact that APMES (3-aminopropyltrimethoxysilane, $\text{NH}_2(\text{CH}_2)_3\text{Si}(\text{CH}_3)_2\text{OCH}_2\text{CH}_3$), which has only one hydrolysable group, leads to relatively intensive spots suggests a dimerization of the molecules. This indicated that there is an interaction between the protonate amine function and the substrate surface, which has been mentioned by several authors (Böhmler *et al.*, 2011; Michelot *et al.*, 2015). So, it is necessary to ensure that the free amine functions required by the following functionalization steps are not all engaged in the silanization reaction. In the case of for RDG motif, Chollet *et al.* have demonstrated an activity for surface densities in the order of $10^{-12} \text{ mol mm}^{-2}$ (Chollet *et al.*, 2009). With this aim, Poli *et al.* have set up sensitive quantification of amine-terminal functions in non-acid media. Two methods have been developed: a modification of the Kaiser method and an adduct method able to quantify primary amine functions down to the $1.0 - 10^{-8} \text{ mol g}^{-1}$ ($\sim 2.0 - 10^{-8} \text{ mol m}^{-2} = 2.0 - 10^{-14} \text{ mol mm}^{-2}$) (Poli *et al.*, 2014).

Immobilization of the Biomolecules

As mentioned above, covalent immobilization routes are based on approaches involving three blocks: (1) a silane presenting free amine function, (2) a cross-linker/spacer and finally (3) the biomolecules of interest (Fig. 2). While the role of the silane is to ensure the junction between the inorganic substrate and the organic structure, the cross-linker agent links the silane to the biomolecule and provides a suitable spacing (Massia and Hubbell, 1991). Two approaches can be distinguished: the “grafting from” approach based on the successive bonding of molecules from the bioceramic surface to the biomolecule and the “grafting to” approach that allows the bonding of a functional building. The latter is constituted by the spacer and the biomolecule of interest, directly onto a silanized surface. Anyway, whatever the approach is, they are based on the same reactions.

The first type of reaction corresponds to the formation of imine bonds between the silane and the crosslinker and between the crosslinker and the targeted protein (or short aa sequence) as illustrated by the left part of Fig. 5. This bond results from the condensation of primary amine and aldehyde functions. Dialdehyde molecules like glutaraldehyde (GA) react with the free amine functions present on the silanized surface, then they will get bound to the biomolecules *via* their amine-terminal groups (Hermanson, 2013; Treccani *et al.*, 2013; Hajimiri *et al.*, 2015). This “grafting from” approach is relatively easy to set up but glutaraldehyde is potentially toxic.

The second group of reactions leads to the formation of amide bonds between the silane and the crosslinker and generally requires the activation of the targeted biomolecule. These reactions need anhydrous solvent and a long set-up. The stable amide bond results from the reaction between the amine-terminal function of the silane with a succinimide function, frequently N-Hydroxysuccinimide (NHS) (Perlin *et al.*, 2008). This approach is illustrated in Fig. 5 (right part) that presents the EDC/NHS strategy (Treccani *et al.*, 2013). The biomolecule is activated by a reaction between its carboxylic acid group and the EDC (1-ethyl-3-(3-diméthylaminopropyl)carbodiimide); then the obtained molecule (O-acylisourea intermediate) reacts with the NHS to provide a reactive NHS-ester function (Durrieu *et al.*, 2004; Schuessle *et al.*, 2009; Poli *et al.*, 2019). Another common possibility is to use the specific reaction between the C=C double bond of maleimide function and the thiol function ($-\text{SH}$) (Lowe, 2014) of the cysteine amino-acid present in the protein or added to the short aa sequence. Different succinimide/maleimide crosslinker agents may be used, offering a large range of possibilities in terms of chain length and approach, *i.e.*, “grafting from” (*e.g.*, (Balasundaram *et al.*, 2006)) *versus* “grafting to” (*e.g.*, (Poli *et al.*, 2019)): SMP (N-succinimidyl-3-maleimidopropionate) (Nelson *et al.*, 2006; Balasundaram *et al.*, 2006), NHS-PEG₆-maleimide (succinimidyl-[(N-maleimidopropionamido)-hexaethyleneglycol] ester) (Damia *et al.*, 2019; Poli *et al.*, 2019). But when all cysteine are linked by disulfide bridges, thiol groups are unavailable to

Fig. 4 Raman maps of silanized HA ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$) and SiHA ($\text{Ca}_{10}(\text{PO}_4)_5.6(\text{SiO}_4)_{0.4}(\text{OH})_{1.6}$) polished ceramics. The two silanes use are the 3-aminopropyltrimethoxysilane (APTES noted M, $\text{NH}_2(\text{CH}_2)_3\text{Si}(\text{CH}_3)_2\text{OCH}_2\text{CH}_3$) and the 3-aminopropyltriethoxysilane (APTES notes T, $\text{NH}_2(\text{CH}_2)_3\text{Si}(\text{CH}_3)_2(\text{OCH}_2\text{CH}_3)_3$). Raman mapping was performed using an inVia Reflex Renishaw Raman spectrophotometer (streamline mode, $\lambda = 532 \text{ nm}$), 50 LWD objective. The maps were reconstructed according to the integrated intensity of the CH modes of both CH_3 and CH_2 units from 2760 to 3060 cm^{-1} . To give an overview of surface properties, three maps of $150\text{--}150 \mu\text{m}^2$ are presented for each condition. react with maleimide function. So in the case of the immobilization of protein that contains no free cysteine amino acid, a thiolation of the protein is required. Traut's reagent is classically used as it reacts with primary amines (of the protein) to form thiols function. The thiol-maleimide coupling will be promoted in anhydrous media, *e.g.*, in the presence of dimethylsulfoxide (DMSO) or dimethylformamide (DMF). Indeed, in aqueous medium with pH above 8, maleimide functions react with amines of arginine or lysine rather than with the thiol group (Brewer and Riehm, 1967). Finally, other crosslinker agents could be used such as a bis-N-hydroxysuccinimide ester of suberic acid (Wang *et al.*, 2008), p-phenylenediisothio-cyanate (Detsch *et al.*, 2009), polyethylene glycol disuccinimidyl succinate (PEG-(SS) 2) (Acharya *et al.*, 2012) or heparin (Goonasekera *et al.*, 2015).

Biological Activity of CPC Functionalized

In vitro and *in vivo* evaluations purpose to evaluate the added-value of functionalization regarding osteointegration and/or angiogenesis stimulation. Most of the authors *in vitro* evaluate the as-obtained biomaterials with osteoblast precursors or human umbilical vein endothelial cells (HUVEC). Nevertheless, as the differentiation of cells is wanting, mesenchymal stem cells (MSC) are more and more utilized since the 2000s. For *in vivo* experiments, the models used are mostly small animal models with *subcutaneous* or bone site implantations depending on the aim, *i.e.*, increasing CPC osteointegration or favoring osteoinduction (Kohli *et al.*, 2018).

In Vitro Evaluation: Adhesiveness and Differentiation

In the beginning of the third generation of biomaterials, the main aim was to increase the cell adhesion. The results presented in this section focus only on chemical functionalization done on CPC materials. Depending on the nature of the attached molecule, cell response has been evaluated from 30 min to 14 even 21 days in culture. Attachment and subsequent adhesion process are relatively short (from 30 min to 24 h), beyond this period the quantitative modifications of cell population *in vitro* are mainly due to cell proliferation events.

As mentioned previously, in comparison with full-length proteins, short aa sequences are less immunogenic, easily synthesized and immobilized onto CPC surfaces, especially by the covalent route. This is why RDG motifs were widely studied: for instance in 2002, Itoh *et al.* have adsorbed E₇PRGDT peptides onto HA ceramics and shown that the peptide stimulated cell attachment and increased DNA content and ALP activity (Itoh *et al.*, 2002). Among the numerous works done on covalent immobilization, the ones of Durrieu *et al.* have to be mentioned (Durrieu *et al.*, 2004). They have indeed shown that it is possible to strongly immobilize RDG sequences on CPC substrates (HA) and they have also highlighted the impact of their sequences on the cell attachment. Cyclo-peptides (c-DfKRG) have been found attractive since they favor cell attachment in short incubation times (3 h) whereas linear RGD peptides (GRGDSPC) allow it at long incubation times (24 h). Later on, it has been shown that RDG sequences improve cell differentiation of murine bone marrow-derived cells line ST-2 (Detsch *et al.*, 2009) and the proliferation of MC3T3-E1 cells (Poli *et al.*, 2019). Interestingly, they also enhance the adhesion of HUVEC. Organic ligands containing cRGDfK as integrin-recognition motif and a pyrogallol unit as anchoring moiety to bioceramics have been adsorbed onto HA and β -tricalcium phosphate (β -TCP) ceramics (Borcard *et al.*, 2012). Functionalized β -TCP ceramics are particularly promising for HUVEC adhesion and adsorption of human proteins, which confirms that the behavior of the RDG motifs used is strongly influenced by the substrate (Perlin *et al.*, 2008). Anyway, the potential of cell-adhesion peptides like RGD in tissue engineering does not reach the end (Huettner *et al.*, 2018).

Concerning full-length ECM proteins, Fn has been shown to act very early in the interaction between cell and material surfaces. When adsorbed at the surface of HA or HA/ β -TCP ceramics, Fn enhance, *in vitro*, the attachment and the adhesion of osteoblastic cells or dermal fibroblasts (Hindié *et al.*, 2014; Kawashita *et al.*, 2016; Matsui *et al.*, 2015; Pendergrass *et al.*, 2012). Moreover, (Kawashita *et al.*, 2016) and (Hindié *et al.*, 2014) have shown that the cell average length or spreading is increased in presence of Fn. When adsorbed, the extent of efficacy of the adhesive effect is dependent on the amount of Fn coated (Matsui *et al.*, 2015) and enhances on a calcium phosphate based ceramic surfaces in comparison with other materials such as alumina, glass or polystyrene (Hindié *et al.*, 2014). The rate of cell proliferation compared to uncoated substrates is not or very slightly ameliorated (Li *et al.*, 2008; Kawashita *et al.*, 2016). Finally, the osteoblastic differentiation evidenced by the activity of the mineralization-associated enzyme alkaline phosphatase (ALP) is not modified by the presence of Fn (Kawashita *et al.*, 2016). Beside Fn, the other ECM protein frequently studied is type I collagen. A study has evidenced that the adhesive properties of collagen has greater influence

than Fn on rat adipose derived stromal cells when adsorbed on HA/ β -TCP 70:30 substrates (Li *et al.*, 2008). In the same approach as the ones used for RDG sequences, Hennessy *et al.* have compared the effect of collagen I and its mimetics short peptides (DGEA or GFOGER) when adsorbed onto HA disks (Hennessy *et al.*, 2009). Collagen and its derivative have a positive effect on expression of osteogenic markers (osteocalcin) and on the enzymatic activity of mineralization-associated alkaline phosphatase, suggesting that they improve osseointegration of HA by stimulating osteoblastic differentiation of MSC rather than their adhesion. However, Wang *et al.* have obtained different results with no effect on cell adhesion and proliferation of cells seeded on porous HA coated with collagen *versus* HA bare scaffolds (Wang *et al.*, 2016). Finally, the case of MEPE (matrix extracellular phospho-glycoprotein), a non-collagenous ECM acid phosphoprotein, is notable (Acharya *et al.*, 2012). The results obtained *in vitro* for the free peptide on human BMSCs (on mineralization) and the expression of the osteogenic marker genes have been confirmed *in vivo*: functionalized HA/ β -TCP particles have been found to enhance bone regeneration in the calvaria defect model in mice.

Biological effect of chemotactic GF on progenitor cells can be evidenced *in vitro* by transwell or Boyden chamber assays. The fast release of SDF-1 α immobilized with alginate and coated onto porous HA scaffolds elicited a strong migration of bone marrow MSC and a good attachment of the cells. However, SDF-1 α does not seem to influence the cell differentiation behavior (Zhang *et al.*, 2018), which is in accordance with other assays performed with non-ceramic materials (Shen *et al.*, 2016). Concerning BMP2, the osteogenic differentiation is dependent of the functionalization route (*i.e.*, adsorption or covalent immobilization) and on the substrate nature. This is directed related to its release kinetics that can be evaluated by biochemical dosages using spectrophotometry (Feito *et al.*, 2010), ELISA (Wernike *et al.*, 2010; Dou *et al.*, 2019) or radiolabeled GF for PDGF-BB (Bateman *et al.*, 2005), VEGF (Wernike *et al.*, 2010; Crouzier *et al.*, 2011) and BMP2, both *in vitro* (Crouzier *et al.*, 2011) and *in vivo* (Tazaki *et al.*, 2009). The release of VEGF immobilized at the surface of BCP disks has been tested alone and in presence of murine bone marrow cells. No modification has been observed except when the osteoclastic differentiation has been induced, in this case the VEGF release was promoted (Wernike *et al.*, 2010). Concerning BMP2, the retention of its biological activity after adsorption or covalent immobilization onto material surface has been tested using a light-promoted reporter system. It is active when BMP2 associated intracellular signaling cascade is activated and effective in responsive cell lines, C2C12 myoblasts or murine mesenchymal cells (Crouzier *et al.*, 2011; Damia *et al.*, 2019). BMP2 has been demonstrated to not or slightly positively affect cell adhesion and proliferation of C2C12 cells (Abarrategi *et al.*, 2012; Crouzier *et al.*, 2011). Elsewhere BMP2 strongly affects the activity of ALP whether it is directly adsorbed to the surface of ceramic materials (Wang *et al.*, 2016), or immobilized using a polyelectrolyte multilayer film (Crouzier *et al.*, 2011). Regarding the use of FGFs in an osteogenesis induction purpose, FGF-1 or FGF-2 adsorbed on silicated HA scaffolds have enhanced adhesion and proliferation of human osteoblastic cells without inducing cell death, associated with the activation of a specific molecular pathway involving the modification of the intracellular flux of calcium (Feito *et al.*, 2010; Wang *et al.*, 2016). PDGF-BB adsorbed on β -TCP also strongly induces the proliferation of human primary osteoblasts (Bateman *et al.*, 2005). Importantly, in the latter case, there exists a synergy between the adsorbed PDGF and the substrate where the cell proliferation is stimulated. Direct or indirect strategies aiming at enhancing biomaterial vascularization use to test the capacity of endothelial cells to proliferate and migrate. *In vitro*, HUVEC are used most of the time. Cell proliferation and migration are both hallmarks of endothelial cell activation enabling new blood vessels to be built. Hence, it has been shown that they are stimulated by VEGF immobilized onto HA, BCP and β -TCP surfaces. VEGF has also been shown to efficiently induce HUVEC differentiation, which has been tested by the mean of tubulogenesis assays, with a better effect obtained with β -TCP over HA (Chen *et al.*, 2015). In the same study, it has also been shown that VEGF promote the secretion of pro-angiogenic factors by human fibroblasts. Finally activation of endothelial cells by angiogenic GF is reflected by the expression of genes and proteins associated with angiogenesis such as the VEGF receptor KDR, or the NO producing enzyme eNOS (Chen *et al.*, 2015; Li *et al.*, 2018).

In Vivo Osteogenic and Osteointegrative Properties

In vivo, osteogenicity of chemically functionalized scaffolds is often tested by histomorphometric analysis of the scaffold after an ectopic implantation for a duration of at least 14 days (subcutaneous or intramuscular) in small animal models such as mice, rats and rabbits (see *e.g.*, (Liang *et al.*, 2005; Saito *et al.*, 2004)). The efficiency of ceramic (HA, substituted or not, β -TCP or BCP with different HA/TCP ratio) functionalization with adsorbed or covalently immobilized BMP2 is reflected by an increase of ALP activity in tissues surrounding the implant (Alam *et al.*, 2001; Liang *et al.*, 2005; Levengood *et al.*, 2010). An absence or a slight presence of connective or fibrous tissue, an infiltration of active immune cells and the presence of ectopic bone formation (Alam *et al.*, 2001; Tazaki *et al.*, 2009; Crouzier *et al.*, 2011) associated with the formation of blood neo-vessels (Liang *et al.*, 2005) and marrow cavities (Abarrategi *et al.*, 2012; Liang *et al.*, 2005) can be observed. Moreover Liang *et al.* have observed the action of BMP2 on the homing of endogenous MSC to the site of implantation, although this phenomenon seems to be delayed on the non-functionalized scaffold (Liang *et al.*, 2005). The quicker the BMP2 is released, the weaker the osteogenicity is (Tazaki *et al.*, 2009; Crouzier *et al.*, 2011). Conversely to Tazaki *et al.*, Alam *et al.* (Alam *et al.*, 2001) have found that when BMP2 is immobilized on porous HA the induction of new bone formation is stronger than with BCP having various HA/TCP ratios. In all the cases, no or slight ectopic bone formation was demonstrated *in vivo* for all scaffolds alone (Alam *et al.*, 2001). In the study of Lin *et al.* (2019a), the nature of the surface of the scaffold has been found to influence the amount of bone formation after subcutaneous implantation in rats. *In vivo* a sequential release with a burst of VEGF and a more sustained liberation of BMP2 leads to a better osteogenesis (subcutaneous site in the rat model), in comparison with scaffolds loaded only with an osteogenic GF such as BMP2 (Dou *et al.*, 2019).

Osteointegrative properties can be evaluated by implantation in long bone (*e.g.*, tibia), calvaria or mandibulae defects (Saito *et al.*, 2006; Abarrategi *et al.*, 2012; Schopper *et al.*, 2008). Positive osteointegrative effects of BMP2 have been shown in dogs with respect to the dose (Yuan *et al.*, 2001). By sequential injection of fluorescent dyes that accumulate on the site of the new mineralized bone apposition, the positive effect of BMP2 in the enhancement of bone formation kinetics *in vivo* has been assessed by Schnettler *et al.* (2008) and Schopper *et al.* (2008). The improvement of osteointegration has been preserved by BMP-2 mimetic peptide deriving from the “knuckle sequence” (Saito *et al.*, 2006). Nevertheless the kinetics of bone formation presented in the rodent models suggest that ectopic formation in small animals is not representative of the ones occurring in larger mammals (Pearce *et al.*, 2007; Hollister and Murphy, 2011; Evans, 2011). Interestingly, after having validated the osteogenicity of BMP2 coated HA ceramic scaffolds in an ectopic site in rabbit, in order to test the osteointegrative properties of their system, Abarrategi *et al.* have compared two different animal models, rabbit and minipigs, in orthotopic implantation assays (Abarrategi *et al.*, 2012). The study puts in light the enhancement of osteointegration of HA scaffolds when associated with BMP2 in comparison to bare HA and to the absence of implant, whatever the animal model is. Better qualitative (bone neoformation, histological structure with presence of blood vessels and bone marrow) and quantitative (amount of bone neo-formation) results have been obtained in presence of BMP2. The study of Abarrategi *et al.* has not evidenced any impact of the scaffold nature upon osteointegration in minipigs. BCP particles coated with PDGF have shown a better osteogenicity in a human model of alveolar bone ridge augmentation (Santana and Santana, 2015). Positive results with the same approach have been also described in a dog model of bone defect (Irokawa *et al.*, 2010). However in a model of rat calvarial defect, the implantation of commercial ceramic bone substitutes (β -TCP and HA) adsorbed with PDGF have given mixed results compared to bare CPC with no or few differences (Luvizuto *et al.*, 2016; de Oliveira *et al.*, 2017).

The stimulation of neovascularization has elicited scaffold colonization by new blood vessels (size and density). In this study, dual releases systems have been used, in which VEGF was adsorbed onto the surface of ceramic HA/collagen composite scaffolds associated with BMP2 loaded in carboxymethyl chitosan microspheres (Dou *et al.*, 2019). The nature of the material employed modifies the biological response, hence the impact of VEGF on β -TCP is superior than on HA. As evidenced by immunofluorescence stainings, more micro-vascular vessels are formed on the scaffold implantation site and more angiogenic factors are produced by resident cells in response to release of VEGF (Chen *et al.*, 2015; Wernike *et al.*, 2010). In this work, two complementary methods have been used: the intravenous injection of FITC-dextran allowing the visualization of vascular network by fluorescence microscopy and a quantitative microscopic analysis using a specific histological index, which is the functional capillary density (FCD) defined as the total length of the erythrocyte perfused capillaries per area (Wernike *et al.*, 2010). The dosage of markers associated with bone and vascular differentiation in tissues around/in the scaffolds give also quantitative information about the efficiency of the employed strategy (Wallner *et al.*, 2015).

Bone pathologies due to the aging of the population are a major problem. In this context, GF-modified scaffolds are promising for the cure of diseases like osteoporosis. Hence, Plaza *et al.* have tested fibronectin-coated HA in a steroid-induced osteoporotic rabbit model with positive results (Plaza *et al.*, 2016). In addition, Wallner *et al.* have used a model of critical defect in diabetic mice (Wallner *et al.*, 2015). Gu *et al.* have tested HA functionalized with TGF-beta and IGF-1 for cervical intervertebral fusion in goat on a 12-week time. The fusion was efficiently achieved in the group implanted with GF-coated HA (Gu *et al.*, 2016).

Lastly the OIM strategies employing chemically grafted GF and/or CK have been, to our knowledge, done with hydrogels or polymer-based materials with positive results *in vitro* and *in vivo*. However, Li *et al.* have sequentially activated human primary macrophages *in vitro* towards the M1 phenotype and then they have switched to the M2 phenotype (Li *et al.*, 2018). This has been assessed by the detection of specific markers and the identification of backsecreted GF and CK (VEGF, PDGF and SDF-1 α). IFN- γ has been adsorbed on composite scaffolds made with calcium silicate and β -TCP. On one hand, the burst release of IFN- γ aims at stimulating M1 activation, and the silicon released from material degradation to obtain M2-polarized macrophages. This allows for the activation of HUVEC cells without altering cell viability *in vitro*. The structures have been proven to be osteogenic *in vivo* with good vascularization, which is promising regarding the novelty of this strategy.

Conclusion

The goal of the chemical functionalization of calcium phosphate bioceramics is to develop the third generation of biomaterials aiming an improvement of the interactions between the biomaterial and its environment. The library of well-characterized natural or derived molecules available for improving the biological properties of biomaterials for bone tissue engineering is rather large. The possibility of synergistic effects associated with the combination of different molecules further increases the possibilities. The choice of associated molecules obviously depends on the targeted biological mechanism. It should be noted that the association of a type of molecule with a given type of material has to be taken into consideration. The works presented here claim to promote the adhesion, the proliferation and the differentiation of the bone cells or to induce angiogenesis, a prerequisite for viable bone growth. So proteins and short aa sequences involved in cell adhesion, osteogenesis and angiogenesis processes are deployed. The routes of functionalization are various and mostly based either on direct adsorption or on covalent immobilization using different agents. Adsorption is relatively well referenced (proteins/substrate interactions, modeling of protein conformations) but questions remain concerning the “bond” between CPC substrates and silane in “covalent immobilization”. Anyway, whatever the chosen route, the targeted biomolecule will be modified. The conformation is modified by the adsorption mechanism and the functions of the covalent immobilization, so its behavior has to be carefully evaluated. Moreover, to be close to the “reality”,

the release kinetics of the biomolecules must be determined in bone physiological conditions, *i.e.*, with a very low flow. The promising approach of osteoimmunomodulation (OIM) is gaining an increasing interest. It is indeed mostly tested on CPC, using their chemico-physical and topography properties to trigger immune cell activation instead of chemical functionalization routes. Therefore, a synergy gathering both these strategies has to be investigated. To conclude, the present chapter and the related results (*in vitro* and *in vivo* experimentations) highlight that functionalized CPC are promising prospects for the induction of bone regrowth after surgery. However, since these devices are intended to be used in humans, the regulatory aspects should be considered at each stage of the development of these materials.

Introduction

Surface functionalization in biomedicine and in tissue engineering has become an expanding field with steadily growing in complexity and involved methods during the last decades. Especially for artificial implants, surface functionalization by chemical or physical treatments or by applying functional coatings has reached a level where chemical composition, release kinetics, resorption behavior, and tissue reaction provoked by a specific surface bioactive behavior can be exactly tuned on a molecular level. Development progresses as new scientific insights arise. The complexity is not at last a demanding challenge as the field is a truly interdisciplinary one, bringing together experts from rather different fields of knowledge: Cell biologists, surgeons, dentists, material, process engineers, physicists, and chemists.

Nearly all available modern surface treatment technologies are involved to alter and functionalize surfaces of surgical instruments, functional implants like electrodes, staying in the human body permanently or non-permanently, that is permanent implants (endoprosthetic devices) as well as exoprosthesis. Besides tailoring the chemical composition of a surface, surface topology is the second important key of surface functionalization, especially for implants that are in direct contact with living tissue. Surface structuring using electrochemical etching, laser engraving, and plasma treatment or mechanical treatments adjusts the amount and size of a specific pore structure or specially formed roughness cavities. This enables tissue to grow into and anchor on the artificial implant surface.

Surface Functionalization for Biomedical Applications

The material diversity used for coatings comprises more or less all known material types like metals, oxides, non-oxides, calcium phosphate based materials, bioglasses, polymers, and amorphous carbons. This fact is also reflected by the multiplicity of surface coating and treatment techniques to chemically and physically tailored surfaces. [Table 1](#) summarizes most common surface coating and treatment techniques and lists some typical application examples.

Thermal Spray Process

Thermal Spraying (TS) is a thermo-kinetic deposition process and involves intensive heat and mass transfer during coating deposition by melting and acceleration of a solid feedstock. It comprises a whole group of different spray methods and can be divided according to the type of energy source used, either being of electrical or autogenous nature. It also includes some special processes. An overview is given in [Fig. 1](#). In principle, every material that shows a congruent melting behavior without decomposition can be thermally sprayed. This is especially true for most metals, oxide ceramics, some carbides, some polymers, and metal ceramic based composite materials (so called cermets). It is also valid for many bioceramics or bioinspired materials, like calcium phosphate based materials and many derived composite materials.

Thermal spraying shows some technical parallels to welding processes, especially when metal feedstocks in form of powders, wires, or rods are involved. From a historical point of view, both techniques were indeed developed in parallel. However, there are some important differences between welding and thermal spraying. In welding the substrate will always be heated above melting point to form a melt bath and alloying of substrate and coating will occur near the surface. This is not the case in thermal spraying. The substrate temperature will only rise to a moderate or intermediate level in the range of 100–300°C, to name typical numbers. By simultaneous cooling techniques, using compressed air or liquid CO₂, it can even be kept below 100°C. This allows for coating of thermally sensible substrates like polymers (PEEK, CFRP, etc.). In most cases, thermal spray coatings need a properly roughened surface to form appropriate adhesion through a mechanical clamping of the individual spray particles that form the final coating. Of course there may also exist diffusion zones on a microscopic level that contribute to adhesion, but substrate and coating material are clearly distinguishable on the interface.

Flame spraying was invented in the beginning of the 20th century and widely used for spraying metals (powders and wires), whereas atmospheric plasma spraying (APS) was primarily used for aerospace applications in the 1960s and entered a broader industrial level starting in the 1980s. The principle setup of a single cathode plasma spray torch is shown in [Fig. 2](#).

However, APS quickly emerged as a versatile and robust coating technology capable of spraying all kind of refractory materials like refractory metals and oxides. The absence of fuel gases and oxygen insures low chemical alteration of the sprayed feedstock. Further variations of this process include vacuum plasma spraying in evacuated chambers (refer to [Fig. 3](#)). This technology allows for spraying of materials that strongly tend to oxidize under ambient conditions. A good example is titanium (Ti), a well-known material that is widely used as coatings in biomedical applications as well. Biocompatible metals and bioceramic coatings are typically applied by vacuum and atmospheric plasma spraying (VPS and APS) techniques and the related manufacturing chains.

Table 1 Examples for surface coating and treatment techniques

Surface process	Coating type	Material examples	Typical substrates	Typical application examples
Thermal spraying (TS)	Thick film 50–100 μm	HAp, TCP, Ti	Ti, Ti-alloys, stainless steel, oxide ceramics, PEEK	Joint replacement implants: Improve bone ingrowth
Physical vapor deposition (PVD)	Thin film 1–5 μm	TiN, ZrN	CoCrMo, stainless steel	Artificial joints: Wear and corrosion protection
Chemical vapor deposition (CVD)		Amorphous carbon DLC	CoCrMo, stainless steel	Artificial joints: Wear and corrosion protection
Electrochemical deposition (ED)		HAp, TCP, Ti	Ti, Ti-alloys	Mainly for dental implant, dental root surface
Sol-gel		HAp		
Electrophoretic deposition		HAp		
Electrolytic plasma oxidation	Surface conversion	TiO ₂		

**Fig. 1** Classification of thermal spray process types according to the type of energy source used, together with appropriate feedstock types (P, W; Sus and Sol).

Flame spraying on the other hand further developed in the later 1980s, when high velocity flame spraying (HVOF) appeared as a new spray method producing high particle velocities. HVOF produces a supersonic jet of combustion gas. Injection of fine powders leads to supersonic particle speed as well, resulting in well adherent and dense coatings. In most industrial applications however, HVOF is used to spray metal and cermet coatings for demanding wear and corrosion protection applications. The typical setup of a HVOF torch is outlined in Fig. 4.

Feedstocks for thermal spraying are mostly available as fine powders or engineered agglomerates, but also as rods and wires depending on the characteristics of the underlying spray material. With the turn of the millennium, a new type of feedstock caught interest within the thermal spray community. Liquid feedstocks opened up a new field of applications and material compositions. Suspension spraying either uses the plasma spraying or flame spray process, called suspension plasma spraying (SPS) and high velocity suspension flame spraying (HVSFS), respectively. In order to spray a liquid feedstock appropriately, modifications in the feeder system as well as in the torch injection and combustion chamber have to be done (see Fig. 5). Analogous to suspension spraying, a liquid feedstock containing a liquid precursor (for instance salts, metal-organics, etc.) can be sprayed, interestingly leading also to fine grained but splat like structures in the coating. As to be discussed in Section “Examples of Research and Development Topics”, liquid feedstock spraying has become one of the central approaches for creating novel biomaterial coatings using SPS and HVSFS. The use of liquid sub-micron and nanoscale suspensions of ceramic powders and the injection through the combustion chamber with subsequent expansion of the particle loaded hot gas jet towards the substrate allows a completely

different thermal and dwell time management of the core process. As a result novel thin solid layers with high density and good adhesion as well as with very fine microstructure can be obtained.

Thermal spraying in general produces coatings regarded as thick coatings typically in a range starting at 50 μm and going up to several 100 μm . Some technical applications demand even thicker coatings, entering the mm range. One of the best examples is TBC coatings, composed of yttria-stabilized zirconia applied in the hot section of gas turbines. Plasma spraying is one of the most successful methods to fulfill this demand, as the coatings exhibit a certain level of fine distributed pores and multi lamellar structures, somehow reducing the stiffness and brittleness of the material, therefore allowing higher coating thickness. The porosity however, is beneficial especially when applied as a TBC material, as it further reduces the thermal conductivity within the coating material. On the other

Fig. 5 Schematic setup for suspension spraying either using the HVOF or the APS process.

hand, by spraying nano- and μ -sized particle containing suspensions using SPS or HVSFS, a downscaling of coatings became possible, as splat dimensions are one to two magnitudes smaller compared to standard APS spray processes. Covering and uniformly structured coatings in the range of 10–50 μm become possible recently, opening up new application fields and coating properties.

Thermal Spraying of Biomaterials

Thermal spraying of biomaterials dates back to the 1970s of the last centuries. First applications reported in literature were CaP coated tooth implants and APS was the preferred coating method. In 1986, plasma spray coatings for the stem of hip endoprotheses in hip joint arthroplasty were introduced to accelerate and improve their ingrowth behavior. The biocompatibility of these coatings enabled the press fit type of hip operation in comparison to the traditional cementation. Coatings on other implant types like shoulder and knee joint replacement parts followed during the ongoing decades. VPS techniques became the preferred method for coating of bone implants with titanium and subsequent top coatings. Recently PEEK implants for spinal therapy (anterior cervical discectomy and fusion) are successfully plasma-spray-coated (Robotti, 2012). Typical application fields are depicted in Fig. 6.

At present, atmospheric plasma spraying and vacuum plasma spraying using specially manufactured spray powders are the two processes to apply various biocompatible materials on metal and polymer implant bodies. Mostly used spray materials in commercially available applications are titanium (Ti) or hydroxyapatite (HAp).

By studying the current literature, research has promising results using suspensions to extend the material palette by introducing bioglasses and glass ceramics. The use of fine grade submicron or even nano-sized powders allows for some new types of coating structures: Either being thin and dense or open porous. Suspension spraying, using either the plasma or the high velocity flame spray process are under intensive research. An overview is given in Table 2.

Classification of Biomaterials Used in Thermal Spray Applications

Every artificial material that enters the body causes a specific reaction of the human body, depending on its chemical nature. Especially metals can undergo a corrosive attack in the body induced by the surrounding fluids and tissues. This can cause severe toxic or allergenic reactions by the body leading to inflammation that may imply a serious health threat for the patient. A second reason is a mechanical attack of joints or joint parts that produces wear debris that distributes into the surrounding tissue. Corrosion and wear can, of course overlay, thus potentiating their effects.

However, regarding the case that none of these problems would occur and the material stays intact, most materials can be classified into four groups showing a typical behavior in or towards living tissue. The material classification is summarized in Fig. 7. Bioceramics, however, represent a special group of materials and were found to be suitable as a thermal spray feedstock as they show a rather stable melting behavior. Most materials used as thermal spray coatings are classified as bio-inert or bioactive. Table 3 gives a summary of thermally sprayed materials, which can be practically divided into four groups:

- (1) calcium phosphates;
- (2) oxides;
- (3) metals, predominantly Ti; and
- (4) bioglasses and glass-ceramics.

Table 3 Overview of biomaterials used in thermal spray based biomedical applications

Material	Composition	Material type	Biorelated properties
Hydroxyapatite	$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$	Calcium phosphate (CaP)	Bioactive, bioconductive, porous ingrowth
Tricalcium phosphate	$\text{Ca}_3(\text{PO}_4)_2$	Calcium phosphate (CaP)	Bioactive, bioresorbable
Titania	TiO_2 , TiO_{2-x}	Oxide, suboxide	Bioinert
Titanium	Ti	Metal	Bioinert, porous ingrowth
Bioglasses and glass-ceramics (AW, 45S5, GB14, ...)	General composition: $[\text{SiO}_2]_x [\text{P}_2\text{O}_5]_y [\text{CaO}]_z [\text{Na}_2\text{O}]_v [\text{K}_2\text{O}]_w [\text{MgO}]_w \dots$	Si, P-glasses	Bioactive, bioresorbable

Table 4 Calcium phosphates used for thermal spray coatings

Name	Chemical composition	Abbreviation	Ca:P ^a molar ratio	Solubility at 37°C ^b [$-\log(K_s)$]
Dicalcium phosphate, brushite	$\text{CaHPO}_4/\text{CaHPO}_4 \cdot 2(\text{H}_2\text{O})$	C ₂ P	1	7.02/6.63
Tricalcium phosphate	α , β , γ – $\text{Ca}_3(\text{PO}_4)_2$	C ₃ P	1.5	25.5 (α), 29.5 (β)
Hydroxyapatite	$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$	HA, HAp	1.67	117.2
Tetracalcium phosphate	$\text{Ca}_4\text{O}(\text{PO}_4)$	C ₄ P	2	37–42

^aJuhasz (2012).^bEliasz (2017).

All four groups are discussed in more details in the following Sections “Calcium Phosphate Based Bioceramics”, “Bioglasses”, “Glass-Ceramics”, “Oxides”, “Titanium”.

Calcium Phosphate Based Bioceramics

By far the most prominent group of biomaterials are calcium phosphate based ceramics. Calcium phosphates (CaP) have Ca^{2+} and phosphate groups $(\text{PO}_4)^{3-}$ or $(\text{PO}_3\text{H})^{2-}$ as their main constituents, in some cases further modified by $(\text{OH})^-$ groups or organized in a hydrated form. Well known representatives are: Tricalciumphosphate (TCP) and hydroxyapatite $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, usually abbreviated as HA or HAp. It is closely linked to the fluorapatite, where $(\text{OH})^-$ is replaced by F^- , forming $\text{Ca}_5(\text{PO}_4)_3\text{F}$. It has a chemical composition that is very close to the composition of the mineral phase of natural bone. However, the natural bone mineral has a slightly lower Ca:P ratio than 1.67 (therefore, non-stoichiometric) and integrates further elements like Na, Mg, F, etc. In dense form (for instance sintered or as a dense coating), it is rather stable in biological surroundings, showing very low solubility or resorption.

TCP exists in three polymorphs, named α , α' and β . The rhombohedral β -form is the stable room temperature phase and the monoclinic α - and hexagonal α' are the two high temperature forms. TCP is bioresorbable with a lower density and a relatively higher solubility of the metastable α and α' forms.

Dicalcium phosphate (C₂P) and Tetracalcium phosphate (C₄P) are further chemical compounds that belong to this group. As summarized and depicted in Table 4, the Ca/P ratio is one of the important factors, as it determines the solubility of the CaP and thus its chemical behavior in a biological surrounding, primarily its bioresorbability.

It should be emphasized here that solubility in general is strongly dependent of the surrounding medium (its pH value, physiological composition and temperature) as well as the morphological structure of the CaP material, will say: Grade of crystallinity, grade of porosity, and amount of exchange surface. It should be noted that an amorphous structure shows a significantly higher solubility than crystalline phases. This partial solubility is of high importance for the reaction with osteoblasts at the phase boundary after operation and during the convalescence period.

CaP based materials are widely used as cements, pastes, and as filler application in dental repair and bone healing and bone replacement procedures. TCP and HAp coatings, often applied by thermal spraying, are widely used in orthopedic, dental and maxillofacial applications (see sections “Examples of Commercially Available Applications” and “Examples of Research and Development Topics”). As they are chemically similar to the mineral component of human bone and hard tissue, they support bone ingrowth and osseointegration, because they are able to form a direct bond to the surrounding hard tissue. It is generally agreed in clinical practise, that these materials are able to shorten the healing process in patients with metal-based implants. TCP is mainly used as a bioresorbable material in certain applications. It dissolves and is replaced on site by natural bone tissue within some weeks. HAp remains more stable as a coating and may be resorbed/transformed to natural bone tissue on a month or year time scale. In any case, it should be understood that the coating is more than just a compatible bond to the remaining bone structure but to some extent a bioactive materials that transforms to natural bone, thereby enhancing the mechanical bond of a prosthetic device to the surrounding hard tissue.

Fig. 8 Left side: CaO/CaP phase diagram showing possible routes for formation of CaP species depending on CaO content and temperature. Right side: Molten HAp particle in plasma spray process with formation of byproducts due to thermal decomposition reactions that occur inflight. Reproduced from (Left side) Heimann, R.B., 2013. Structure, properties and biomedical performance of osteoconductive bioceramic coatings. *Surface and Coatings Technology* 233, 17–38. (Right side) Dyshlovenko, S., 2004. Numerical simulation of hydroxyapatite powder behaviour in plasma jet. *Surface and Coatings Technology* 179, 110–117.

Most calcium phosphates, especially HAp can be synthesized in many ways using precipitation reactions, sol–gel processes, flame synthesis, or by extraction from animal bone based natural sources. The same is true for applicable coating methods. HAp coatings can be fabricated using several PVD techniques, by sol–gel method, electrophoretic deposition and last, but not least by the use of thermal spray processes, namely plasma (APS, VPS) or flame spraying (FS, HVOF, HVSFS), using exclusively fabricated HAp spray powders and engineered suspensions.

Thermal spraying of HAp or TCP always leads to the formation of accompanying species due to molecular fragmentation. The reason for that is that the spray material undergoes phase transitions by melting, partial evaporation, and subsequent quenching process with high cooling rates on the substrate. As these phase transitions do not occur under thermodynamic equilibrium conditions, there is always a certain probability to obtain a mixed phase coating product, including metastable species. On the other side this diversity gives an additional tool to the materials engineering to tailor the bioresorption and biocompatibility. Although the main phase in the coating consists of crystalline HAp, the material partially undergoes a thermal decomposition by spalling off OH[−] and P₂O₅[−] groups (refer to Fig. 8). This leads to the formation of further species like α-TCP, oxyapatite (OA) and oxyhydroxyapatite (OHA) that can be found in the coating. At high temperature levels, possibly the formation of undesired CaO is enabled. The high cooling rates lead to a certain amount of amorphous phase, as can be recognized. For instance in XRD spectra.

Bioglasses

The invention of bioglasses dates back to 1969 when Larry Hench and co-workers published first results about the high compatibility and bioactive behavior of specific types of reactive silicon-based glasses, also containing Na₂O, CaO, P₂O₅ as main constituents. The first commercially available bioglass was called 45S5 Bioglass® and had a unique composition of 45% SiO₂, 24.5% Na₂O, 24.4% CaO, and 6% P₂O₅. Bioglasses are generally highly reactive and bioresorbable. This is also reflected by the high Ca:P ratio. For 45S5, it is in the range of 5. In simulated body fluid and in adequate in vivo environment, their surface transforms to dense Hap surface reaction layers. This beneficial effect is exploited for the transformation of porous bioglass structures to Hap or the stimulation and ingrowth of natural bone and hard tissue in various implant structures.

The production of such glasses is according to standard glass manufacturing routes. A key issue is the high purity of the material that has to be maintained throughout the entire manufacturing route. The manufacturing of medical parts includes sintering of components, tempering, and injection molding by use of glass powder containing feedstocks with subsequent tempering. Thermal spraying of glass powders is possible, especially by using flame spray processes.

Soon after publication of the first type of the 45S5 glass, Hench, D. Day and others were developing further variants of bioglasses, using the basic constituents (SiO₂, Na₂O, CaO, P₂O₅). It can be regarded as a kind of chemical construction kit (Hench, 1991). Fig. 9 illustrates that a tailoring of bioglasses is possible in a wide composition range depicted as A, where the glass composition is able to form a direct bone contact. Other compositions (For instance region S in Fig. 9) favor soft tissue formation at the interface. The basic formulation can be further enhanced by adding further oxides like potassium (K₂O) or magnesium oxides (MgO). Thereby, constituents may act as network former or network modifier. Addition of P₂O₅, for instance acts as a network former and integrates into the Si–O tetrahedral network. Na⁺, K⁺, and Ca²⁺ for instance act as network modifiers. At

present, some dozens of commercially available bioglass types exist and much more are under investigation in research labs. Four well-known examples are shown in [Table 5](#) including the 45S5 type.

The bioactivity of bioglasses is closely linked to their specific dissolution behavior in living tissue. Systematic research of the complex kinetic and chemistry uses so-called simulated body fluid (SBF) tests to observe dissolution and precipitation reactions occurring when a bioglass material is exposed to body like environment, the typical composition is given in [Table 6](#). By immersion of bioglass samples or coated surfaces into the solution and by tracking composition as well as the precipitation reactions that will occur on the glass surface as a function of time (in days or weeks), the reaction behavior of a specific bioglass composition can be characterized. Bioactive behavior involves some typical steps including:

- Fast dissolution of cations out of the glass and replacement by H ions. Thereby the pH value of the solution increases.
- Loss of silica in the glass network and subsequently formation of a silica layer on the surface.
- Migration of cations (Ca²⁺, PO₄³⁻) to the bioglass surface through the silica rich layer forming amorphous CaO/P₂O₅ rich films.
- Crystallization and forming of HAp / HCA layer (HCA: Carbonated hydroxyapatite).

For a more detailed description of the mechanism, please refer to [Hench \(1993\)](#). Despite its excellent bioactive properties, the major disadvantages of bioactive glasses are their low mechanical strength and low fracture toughness. These characteristics restrict their use to a few applications, that is as fillers in dental bone repair. To improve the mechanical performance, bioactive glass-ceramics have been developed.

Glass-Ceramics

Glasses that contain a certain amount of crystalline phase dispersed in their glassy matrix are called glass-ceramics. The kind and amount of crystalline phase and thus the final properties of the glass-ceramic material can be controlled by the initial glass composition as well as by a controlled heat treatment. Some types of glass ceramics are based on calcium alkali orthophosphates $\text{Ca}_2\text{KNa}(\text{PO}_4)_2$ and degrade faster than TCP. The most well-known commercially bioactive glass-ceramics are Ceravital®, Bioverit®, and A/W Cerabone® (for composition refer to Table 7).

Ceravital® is composed of a glassy phase, containing devitrite and apatite crystals. The main application of this glass-ceramic is as substitute of the ossicular chain in the middle ear. In addition to the glassy phase, Bioverit® is composed of apatite and mica crystals, which are responsible for its excellent machinability. Bioverit® implants are mainly used as spinal spacers and in head and neck surgery. The A/W Cerabone® glass-ceramic is composed of an apatite matrix reinforced by needle-like wollastonite crystals, possessing highest fracture toughness values among all of the bioactive glass-ceramics. Among other applications, A/W Cerabone® has been used as iliac crest bone graft with great success. It is also known as A/W glass-ceramic and contains crystalline phases of apatite and β -wollastonite in a glassy matrix. It was originally developed by Kokubo in the late 1980s (Kokubo, 1993).

All three mentioned glass-ceramics are composed of an apatite-like crystalline phase, which is much less soluble than bioglass, for instance 45S5. Although glass-ceramics in general exhibit a better mechanical performance than bioglasses, their bioactivity level is lower than of pure bioglasses but higher than typical crystalline CaP ceramics like HAp. This has been investigated in a famous comparative study by Hench (1991) and results are summarized in a rather popular graphic shown in Fig. 10.

Bioglasses and glass-ceramics can both be sprayed using plasma and flame spray techniques. Although not yet established in clinical practice, both material groups are under intensive investigation as promising candidates for bioactive coatings mainly for bone implants.

Oxides

Spraying oxides using plasma or flame spray methods is a well-established method to manufacture thick and well adherent oxide based coatings on metal substrates for many industrial applications. Oxides to be considered for medical applications are titanium oxide (TiO_2), zirconium oxide (ZrO_2), and aluminum oxide (Al_2O_3). These materials are regarded as bio-inert and support the formation of direct bone tissue contact in dental or bone implants. Recent studies showed a distinct osteoconductivity for TiO_2 coatings. For most medical applications, these oxide materials (Al_2O_3 and ZrO_2) are not used as coatings but as sintered bodies.

This is not the case for titanium oxide, as it exhibits very interesting features when applied as a coating (Liang, 2019). TiO_2 coatings can be created employing many different manufacturing routes like PVD, CVD, sol-gel, anodizing techniques, and plasma or flame spraying techniques. Each method creates unique surface structures and different crystalline phase compositions. TiO_2 exists in two main crystalline phases, anatase and rutile (brookite, a third phase is of minor importance). They often coexist in different ratios and strongly determine the physical and chemical behavior of the coating. For medical applications, this is for instance the wetting behavior against aqueous media. It is well known that TiO_2 as anatase exhibits a strong photocatalytic activity when irradiated using visible light or, with an even stronger effect, using UV-A. This can change wettability of the surface from hydrophobic to hydrophilic when irradiated. For implants, especially for dental roots, the wetting with blood plasma is crucial for accelerated protein adsorption and further promotion of osteoblast cell growth and subsequent osseointegration.

Titanium

Although titanium is a metal, it should be considered in this context, as it is widely used in thermal spray applications on bone implants. Titanium generally is regarded as a bio-inert material showing excellent biocompatibility as it always forms a thin oxide layer on its surface. Titanium with high purity (Grade 2 and Grade 3) or titanium alloys for instance Ti6Al4V are also widely used as load bearing structural bone replacements due to its high cycle fatigue behavior (see Section “Involved Substrates”).

Production of high purity titanium powder, which is used in medical technology is performed in two routes: (1) HDH process and (2) gas atomized (molten bath). HDH stands for hydratio–dehydration, which means that through the addition of hydrogen, the source material becomes brittle and can be crushed mechanically. After this process step, the material is then returned to its original metal state by a thermal process under high vacuum that thermally removes the hydrogen (dehydration).

Spraying of porous titanium is currently performed in a vacuum plasma spray process on bone implant structures namely on hip joint implants (femur side). As Ti powder shows a highly chemical reactivity towards oxygen, resulting in exothermal oxidation reaction the entire spray process is restricted to vacuum processes.

Involved Substrates

Thermal spraying is a flexible and versatile coating technology and can be performed on many types of substrates. Among these are all kind of metals, some polymers, all kind of ceramics (silicate, oxide, or non-oxide based), glasses, even a wood surface can be metal or ceramic coated.

In medical applications, thermal spraying is predominantly used to coat permanent implant structures made from metal, polymer, or ceramic materials, with metal bone implants being the main application at present. A number of R&D activities investigate the possibilities to apply coatings on ceramic and polymer substrates for new implant products. In Table 8, most common substrate materials are summarized together with their predominant applications. For metal implants, there exist three main applications, dental implants, bone joint replacement (hip, knee, shoulder, finger, etc.), and spinal implants. Oxide ceramics like alumina or zirconia based materials are mostly used as composites for instance stabilized zirconia (YSZ) as dental routes or zirconia toughened alumina (ZTA) as joint parts in hip, shoulder and knee. PEEK is a material that has been recently introduced as implant for instance in spinal replacement.

Table 8 Implant materials that are suitable for thermal spray coating process

Material type	Material	Main implant applications	Remarks
Metal	Ti grade 2,3,4	Hip and knee joints; dental implants	For less mechanically loaded implant parts. High corrosion resistance
	Ti6Al4V	Hip and knee joints; dental implants	Used for mechanically highly loaded parts
	CoCrMo alloy	Hip and knee joints; dental implants	Used for mechanically highly loaded parts
	Stainless steel 316 L	Hip and knee joints	Nowadays gradually replaced by CoCrMo and Ti
Oxides	ZTA	Sphere for hip joint Cap for hip joint Knee joint	Needs high precision tooling Mounted in metal case Under development
	YSZ	Dental implant	As an alternative to Ti
Polymers	PEEK	Lumbar cages	Mainly spinal implants
	PDLLA Poly-D, L lactic acid	Resorbable screws, plates and foils	Mainly used in maxillofacial surgery
	PLLA Poly-L lactic acid		

Examples of Commercially Available Applications

Dental roots made from Ti were among the first implants that where plasma spray coated using HAp and titanium oxide (Heimann, 2015) (Straumann, Basel CH). Although many other surface treatments of Ti based dental implants exist nowadays on the market, plasma spraying of HAp and TiO_2 is still one of the chosen methods and under further research (van Oirschot, 2016), including clinical studies on patients (Palarie, 2012). In most cases, only the root section that is in direct contact to bone tissue is surface treated (Fig. 11).

Nowadays hip and knee joint implants are the most common application for plasma spraying. All joint implants in general consist of a joint pair that replaces the natural joint. Hip and knee joints are the ones that have to bear highest mechanical load. A durable fixation is of great importance.

In case of the hip joint, it is the femur rod that is anchored in the open cut femur bone. The counterpart is the acetabular shell that is fixated in the pelvis. To fixate the femur rod, two clinical methods have been established in clinical practise and are used alternatively. The first method fixates the implant by cementing it into the bone. This is performed by using polymethylmethacrylate (PMMA) as a glue between bone and implant. In this case, a coating of the implant is not necessary and would not have any benefit. The second method is based on a mechanical fixation of the implant called press-fit by mechanically pressing it into the laid open femur cavity. In this case, the bone tissue is in close contact with the implant surface and in this case bioactive coatings are applied to improve the ingrowth process by active stimulation of bone tissue growth at the implant surface. This leads to a durable connection between implant and bone within some weeks. Plasma spraying (APS and VPS) is the preferred method used on commercial implants. Porous Ti and/or HAp are applied on Ti alloy and CoCr-based implants. Hip implants exist in a wide variety of geometries and designs that are chosen to meet the specific anatomical and clinical conditions of the individual patient. One example of a set of hip implant parts that are plasma spray coated with HAp is shown in Fig. 12.

Knee joints are also inserted pairwise as femur and tibia sided bearings. The strategy is comparable to hip joint replacements, regarding implant materials (Ti alloys, CoCrMo) as well as coating materials. Bioactive coatings are applied to all bone contacting surfaces of the tibia and femur bearing component respectively (refer to Fig. 13). However, most manufacturers also provide sets for cement fixation. In this case, bioactive coatings are not applied. In this case, open porous surfaces are favored by using for instance sintered metal beads or plasma-sprayed Ti (refer to Fig. 14).

Examples of Research and Development Topics

In the last section, some R&D results that were published in recent years are presented, dealing with thermal spraying for biomedical applications.

TCP Coatings on PDLLA Implants

Bioresorbable polymer implants fabricated from poly (D, L-lactic) acid (PDLLA) are often used in maxillofacial surgery as an alternative to Ti implants. The material is a completely amorphous bioresorbable polymer, degraded within the human body into lactic acid by hydrolysis. Compared to titanium, it shows significantly lower mechanical values (bending strength), but in situations where less mechanical load is expected, it can be a valuable alternative, since it is resorbable and thus eliminates the need for a secondary operation that is needed for implant removal.

Biocompatibility of these implants are nevertheless not completely satisfactory, because it is difficult, to properly adjust degradation behavior of the material. A too fast degradation in vivo can lower the pH value in the surrounding tissue, thus leading to irritations and inflammatory reactions. Therefore new composite devices are demanded. Thermally sprayed tricalcium phosphate (TCP) coatings can significantly increase the biocompatibility of resorbable polymer implants and helps to better match the resorption rate of the implant with the bone-healing rate. The manufacturing process of suitable β -TCP powders to be used in atmospheric plasma spraying (APS) via spray-dry granulation and thermal spray coating on bioresorbable PDLLA implant samples were demonstrated (Baccalaro, 2009). An example of uncoated and plasma-coated plates is shown in Fig. 15.

The TCP coating prevents direct PDLLA/bone-tissue contact thus and acts as a dissolution barrier as it degrades more slowly therefore preventing a too fast degradation of the PDLLA material. The plasma spray coating shows a good adhesion and even

Fig. 15 Left: Uncoated PDLLA plate. Center: TCP plasma-coated PDLLA sample. Right: Demonstration of plastic deformation of coated sample. See text for details. Image source IFKB University of Stuttgart.

allows for a deformation of the PDLLA implant during surgery. This can be done by the surgeon on-site by mildly warming up the PDLLA material. It becomes soft and can be bended to match geometrical constraints when doing bone reconstruction in maxillofacial surgery. **Fig. 16** (left side) shows a light microscope image of plasma sprayed TCP showing a well-formed connection of the ceramic to the PDLLA polymer interface. The coating porosity level can be adjusted by plasma spray parameters as well as the phase composition that can range from pure α to a α/β mixed phase (refer to **Fig. 16**, right side). Both values affect the resorbability of the TCP material (resorption rate α -TCP > β -TCP).

Ceramic Coatings on Dental Zirconia Implants

Ceramic dental implants have been introduced in recent years as an alternative to Ti implants mainly for two reasons: Increasing esthetic standards especially for teeth implants and increasing incidence of titanium allergies that exist in a percentage of patients and ask for metal free implants.

Among ceramic materials, zirconia has been the choice as it exhibits excellent biocompatibility and tissue integration, low affinity to plaque, and favorable biomechanical properties. Unquestionable is the high esthetic level that is reached by a zirconia ceramic implant, as it resembles the natural teeth material in any optical aspects. However, a drawback came, when early failures were reported to be significantly higher for zirconia implants than for titanium implants. Technical failure as a result of fracture of the material is also a major concern and material development is still going on. Integration of the material into the bone also is an issue as the implant surface is rather smooth and osseointegration is not as fast as in Ti implants. However, a mechanical roughening of the implant surface is critical, as it may affect the material toughness of the ceramic due to implementation of surface defects.

Fig. 18 Comparison of achieved surface roughness values on plasma-spray-coated ceramic samples before coating in pre-sintered state, after coating on pre-sintered body and after final sintering at 1500°C . Data reproduced from Stiegler, N., 2012. Biokeramische Schichten auf Implantaten durch thermokinetische Beschichtungsverfahren: Thermisches Spritzen von Biomaterialien. In: Gadow, R. (Ed.), *Forschungsberichte des Instituts für Fertigungstechnologie keramischer Bauteile*, Universität Stuttgart. Aachen: Shaker Verlag (ISBN 3844014799)

A possible approach to achieve a rough surface without mechanical treatment was done in a study by applying a plasma spray coating directly on a pre-sintered ceramic body (cross-section shown in Fig. 17(a)). As a mechanical activation of the ceramic surface is not allowed, the coating is performed at elevated temperatures to achieve sufficient adhesion. When final sintering the coated ceramic body at 1500°C , a post densification and increased bonding of the plasma sprayed coating can be observed (refer to Fig. 17(c) and (e)). As depicted in Fig. 18, the roughness values could be significantly increased by this procedure. No change of roughness occurred after final sintering of the samples.

However, it should be kept in mind that when sintering oxide ceramics a significant shrinkage occurs, setting the coating under compressive stress. This can be avoided by choosing an appropriate temperature in the pre-sintering process. In this study 1300°C was found to be high enough to avoid delamination. Coated and sintered flat samples were mechanically analyzed in respect of coating adhesion and mechanical failure of the YSZ ceramic. It was found that the coating process did not affect bending strength and that values were comparable to uncoated samples (in the range of 700 MPa). Coating adhesion was measured on flat samples and reached 55 MPa after sintering. As a conclusion, plasma spraying proved as a reliable process to shape ceramic implant surfaces to a desired structure. Meanwhile industry is offering implant parts made from oxide ceramic and PEEK that are directly coated with a porous Ti coating using VPS (Keramik and PEEK, 2019).

Mechanical properties of suspension plasma sprayed hydroxyapatite coatings submitted to simulated body fluid. *Surface and Coatings Technology* 205 (4), 954–960.

Suspension Spraying of CaP Materials

Since the introduction of suspension-based spraying around the millennium, there was an increasing interest among the research community to develop bioceramics coatings for implant applications. The main goal was to fabricate thin, homogeneous, high quality layers to overcome some of the drawbacks observed in plasma spraying, namely the degradation of HAp and formation of by-products (OHA, OA TCP amorphous CaP, etc.). Suspension spraying also offers new microstructures, namely the formation of nano-structured coatings with a tailored crystallinity. This became possible by direct processing of nano-powders (Jaworski, 2008, 2010). First activities started in the 1990s by plasma spraying of HAp using ICP technology (Bouyer, 1997). Since then, the research activity in this field accelerated, reflected in an enormous publication activity (Killinger, 2011, 2015).

Suspension plasma spraying of CaP materials based on submicron or nanoparticle containing suspensions were intensively studied by Pawlowski *et al.* (Podlesak, 2010; Jaworski, 2008; Łatka, 2010). Morphology of SPS HAp coatings show a typical porous and inhomogeneous structure (refer to Fig. 19) consisting of different areas: (1) unmelted sintered particle form agglomerate zones; (2) molten particles generate splats; and (3) rounded droplets depending on size, impact velocity and temperature. Inhomogeneities are mainly due to different trajectories and thermal histories of droplets within plasma jet when injected radially. A typical coating structure is shown in in vitro testing in SBF (refer to Table 6) shows increased dissolution due to the rather high specific surface area. Selective dissolution of amorphous zones and formation of carbonated hydroxyapatite (HCA) inside pores and defects can be observed.

HVSFS was introduced in 2007 as an alternative coating process for spraying of CaP materials (Gadow, 2010). Like in SPS processing of nano and submicron powders dispersed in suspension is possible. The process is capable to form dense and well adherent coatings of HAp, TCP and bioglass materials. Examples are shown in Fig. 20. The coatings were sprayed using submicron- and nano-scaled feedstocks reaching a film thickness of 20 μm in one spray path. Coating adhesion was in the range of 20 MPa.

In vitro SBF tests showed that higher coating density slows down dissolution tendency compared to SPS coatings. However re-precipitated HAp can be observed but is strongly affected by degree of crystallinity of the coating (Bolelli, 2015). Bioglass coatings also show a higher activity in SBF. In direct comparison to SPS coatings, it can be stated that SPS form silica gel and HAp within the porous coating volume whereas HVSFS coatings form a compact layer of silica gel and HAp layers on top.

In vitro cell tests were performed on HVSFS HAp and 45S5 bioglass coatings using MG63 cells (refer to Bernstein, 2011; Altomare, 2011). Fig. 21 shows SEM images of MG63 cells adhered to the bioglass coating surface after 3 and 7 days for comparison. It was found that no toxic products were released by the coating. Human osteosarcoma cells could well adhere and proliferate onto the surface of 45S5 bioglass. The formulation thus maintains its biofunctionality, when sprayed via HVSFS.

HVSFS Spraying of Metal Doped CaP Materials

An interesting approach is the creation of antibacterially active coatings on implants. This can be acquired for instance by implementation of antibacterial agents like metals into a coating. Release of the agent is then either promoted by bio-erosion of the coating or due to a high surface area if the coating is porous. Some metal ion (Ag) doped HAp spray powders are already available on the market (Medicoat AG, 2019). Another approach is using suspension spraying where metal ions in

form of ultrafine powders or as a salt can be directly mixed with CaP based powders in the liquid feedstock. This is described in Krieg (2017). Suspensions containing HAp, TCP, bioglass, and GB14 were prepared and doped using Cu, Bi, and Ag. Coatings were fabricated using HVSFS and analyzed regarding their metal ion distribution in the coating. It could be shown that a distribution of nano crystals in the CaP matrix is possible (refer to Fig. 22). In vitro cell tests confirm the biocompatibility of the coatings.

In vivo investigations were recently performed by the G.E.R.N. at the Universitätsklinik in Freiburg, Germany. Titanium rods were HVSFS coated and implanted into the femur condyle of rabbits. As an example, Fig. 23 shows the histologic section of HVSFS coated Ti-rod implant after 24 weeks implantation period near the coating interface region. TCP doped with Cu was applied as a coating material. Similar results were achieved using HAp, GB14, and bioglass as a coating material. The image clearly shows a tight connection of the bone tissue to the coating surface and proves the good biocompatibility of the coatings. However, further investigations are necessary to interpret the histological results.

Conclusion and Summary

Functionalization of bone implant surfaces is the major subject of thermally sprayed CaP and Ti based coating materials. A fast ingrowth and a good and long lasting bone–tissue connection are the major goals of this strategy. Bioresorbable coatings can even more stimulate bone ingrowth and tissue formation directly occurring on the implant surface. It is unquestioned that TS coatings have been impressively successful in fulfilling these goals for many decades.

However, there are still remaining issues related to load bearing implants mainly in hip joint replacement. One of the major problems is the loosening of load bearing implants due to a bone remodeling. This is provoked by the altered stress distribution caused by stress shielding of the metal implant. Although the process may take many years, it eventually leads to a progressive depletion of bone tissue and finally to the loosening of the implant. So the problem is not addressed to the interface or the coating itself, but to the mechanical properties of the implant, that causes the stress shielding. To solve the problem, new implant materials have to be found that resemble the mechanical properties of the bone in terms of mechanical stiffness (Young modulus), fatigue strength and density. An interesting approach was done in the late 1990s, when fiber reinforced PEEK materials were under evaluation as an alternative to metal materials for hip implants (Ha, 1997). The material shows distinct advantages compared to metal implants. It behaves artifact-free in radiographic imaging, the lower modulus of elasticity better matches that of bone and fatigue strength is greater than most metal implants. Although the material showed promising results in mechanical testing, a problem remained that could not fully satisfactory solved so far: The proper design of the PEEK surface to ensure the same quality of ingrowth behavior like seen from metal implants. Although used nowadays in several applications like internal and external fixation structures (Scholz, 2011), it has not yet replaced load bearing metal materials in hip implant applications. New concepts for an improved implant–bone interface are necessary and need to be developed.

Functionalization of implant surfaces by adding active agents (antibiotics, growth factors, etc.) that are released post-operative into the surrounding tissue is another concept that is under intense research. One example for this concept, that uses thermally sprayed coatings has been presented in the last section (metal-doped coatings).

Direct fixation of ceramic implants by thermal spray application of bio-inert or bioactive coatings on zirconia or alumina-based implants in knee and hip joints is another field under current development. By a direct anchoring of the ceramic implant to the human bone (for instance pelvis, femur, etc.), metal connecting pieces are becoming fully redundant.

More applications of thermally sprayed coatings are useful in general tissue engineering and flexible scaffolds. Thermally sprayed oxide and bioceramic coatings on various flat and even flexible substrates have shown their promising potential for cell growth in tissue engineering not only with respect to prosthetic devices and a focus on osteoblast and stem cells growth but also for liver cells, skin and cartilage. These in vivo or in vitro cell growth concepts are a further issue of interdisciplinary scientific cooperation with ceramists.

Design of Tissue Engineering Scaffold by Means of Mathematical Modeling

Stefan Scheiner, TU Wien (Vienna University of Technology), Vienna, Austria

© 2021 Elsevier Inc. All rights reserved.

Introduction

In a nutshell, tissue engineering aims at equipping biological tissues with a suitable substrate for tissue regeneration. Thereby, the need for regeneration may have to do with the preceding removal of malfunctioning or pathological tissue. Although tissue engineering is relevant to more or less all biological tissues, this chapter focuses on bone tissue. In bone tissue engineering, a scaffold structure is typically implanted into the patient, taking over the function of removed bone tissue. There, it fulfills two main functions. On the one hand, it is supposed to act as replacement material, taking thus over the load-bearing role of bone tissue. On the other hand, it may also provide the substrate on which new bone tissue can grow. In a best-case scenario, growth of new bone tissue is accompanied by the gradual dissolution of the synthetic tissue engineering scaffold. Hence, in the long-run, the affected tissue becomes again a completely natural material. The related technologies and methods have been developed and honed over several decades, with a number of textbooks and review papers documenting the time course and the evolution of the respective state of the art ([Hutmacher, 2000](#); [Hollister, 2005](#); [Rezwan et al., 2006](#); [Lanza et al., 2007](#); [Williams, 2008](#); [O'Brien, 2011](#); [Geris, 2013](#)).

Adequate integration into the targeted physiological environment requires bone tissue engineering scaffolds to fulfill several requirements. The most important, commonly known ones are biocompatibility, osteoconductivity, biodegradability, and mechanical competence. In particular, the term biocompatibility describes that scaffold materials must not cause any harm to the targeted physiological environment. In other words, it is paramount to not use materials which cause, e.g., inflammations or other adverse reactions. Furthermore, scaffolds should stimulate the regeneration of bone tissue. For that purpose, they must be suitable for hosting bone growth-promoting cells and growth factors, and they must be sufficiently porous, in order to provide enough physical space for substantial ingrowth of bone tissue. If a scaffold material features these characteristics, it is referred to as osteoconductive. The aforementioned desired behavior of dissolving upon substantial ingrowth of new bone tissue is known as biodegradability. Once sufficient amounts of new bone tissue have been formed, degradation and eventual disappearance of the scaffold structure is desirable, as it has then fulfilled the purpose of providing temporary support and is no longer needed. Clearly, the involved degradation processes must not occur too fast, as then the required load-bearing capacity would not be provided anymore. This leads to the last of the above-listed requirements, namely mechanical competence. Bone is often concerned with load-bearing tasks, which is why bone tissue engineering scaffolds must exhibit suitable mechanical properties.

While the first three requirements – biocompatibility, osteoconductivity, and biodegradability – are mainly a matter of choosing appropriate materials, mechanical competence is clearly a topic which can benefit from predictive engineering methods. The scaffold material has to sustain the mechanical loading to which it is subjected, thus it must not be too soft. However, the biochemical processes related to bone regeneration are partly governed by the deformation characteristics of the scaffold ([Simmons et al., 2001](#); [Robling et al., 2006](#); [Jacobs et al., 2010](#)). This implies that for optimal integration of the scaffold into its bony vicinity, it must not be too stiff either, otherwise the biochemical processes involved cannot be initiated or maintained through the prevalent mechanobiological couplings. In the long run, the consequence would be potentially adverse, and phenomena such as stress shielding could occur, which may lead to bone degeneration in the proximity of the implant ([Engh et al., 1987](#)). For that reason, designing scaffold materials and structures with the just right stiffness (that is, not too soft and not too stiff), which is the mechanical property determining the elastic deformation behavior, is a delicate task. In this respect, nowadays much stressed terms come into play, namely patient-specific design or precision medicine, meaning that a scaffold is implanted which fits as well as possible to the biological and mechanical environment which can be found precisely in a specific patient.

Standardly, experimental methods are employed in order to scrutinize new scaffold materials and structures regarding their suitability as to replace a respective piece of bone. While biocompatibility, osteoconductivity, and biodegradability can be tested reasonably well by means of experimental methods, it is extremely challenging to study the mechanical properties of bone tissue engineering materials and structures, in particular when taking into consideration that these properties actually evolve over time. For those reasons, following a more comprehensive approach has been suggested as remedy ([Geris, 2013](#)). In particular, utilizing the predictive capabilities of computational modeling, while also integrating data provided by experimental research and clinical studies, promises to provide a predictive assessment of materials and structures in terms of their performance when applied as bone replacement material. This chapter presents a brief overview of the current state of the art in this field.

A Survey on Mathematical Models Used in Bone Tissue Engineering

The conventional state of the art in the field largely comprises some kind of high-resolution imaging modality by means of which the input for large-scale numerical studies is produced. In particular, the most popular imaging method is clearly computed tomography (CT) or micro-computed tomography (micro-CT), which yields information concerning the three-dimensional distribution of

attenuation coefficients, in terms of attenuation coefficient-proportional gray values. By employing suitable thresholding, the sought-after geometry of the scaffold structure can be deduced (Rüeggsegger *et al.*, 1996).

The mechanical behavior of tissue engineering structures is typically described by a set of partial differential equations. In order to solve such systems of coupled equations, numerical methods are usually employed. A number of different modeling techniques is available for discretizing the shape of the modeled domain and for solving the resulting equations, including the classical Finite Element (FE) method, boundary element methods, meshless methods, isogeometric methods, and more. The most widespread method is undoubtedly the FE method, which is probably due to the fact that commercial FE software is widely available and easy to use. The complexity of the numerical models and the computational costs arising for the simulations depends on the morphology of the studied scaffold. If the latter exhibits some sort of periodicity, so-called unit cell models can be easily created, see e.g. (Adachi *et al.*, 2006; Huttmacher and Singh, 2008; Lacroix *et al.*, 2009; Olivares *et al.*, 2009; Melchels *et al.*, 2010; Sturm *et al.*, 2010; Dias *et al.*, 2012; Truscetto *et al.*, 2012), and Fig. 1(A) for an exemplary model. For irregular microstructures, the aforementioned micro-CT data is often the basis for generation of a corresponding FE model, see e.g. (Jaecques *et al.*, 2004; Porter *et al.*, 2005; Williams *et al.*, 2005; Lacroix *et al.*, 2006; Sandino *et al.*, 2008; Lacroix *et al.*, 2009; Milan *et al.*, 2009; Voronov *et al.*, 2010; Sandino and Lacroix, 2011), and Fig. 1(C). However, the related computation time is substantial, causing severe restrictions as to the applicability of such modeling strategies in clinical environments. As a remedy, so-called numerical multi-scale models have been suggested, where the FE models are comparably coarse, and information from lower observation scales is integrated in homogenized fashion. This strategy is particularly useful if certain domains within the numerical model are subjected to a dynamic evolution, as it is the case if bone tissue is formed in the pore spaces of a scaffold structure (Sanz-Herrera *et al.*, 2008, 2009a,b), see e.g. Fig. 1(B).

From a conceptual point of view, large-scale numerical modeling can be applied to study a wide range of different aspects relevant in bone tissue engineering, including the assessment of local effects occurring in response to physiological mechanical loading, the simulation of the pore fluid movement, see e.g., Fig. 1(D), or the bone regeneration performance over time. The significance of these simulations is directly related to the reliability of the input parameters fed into the numerical model. This concerns in particular the mechanical properties. The simplest approach in this respect is to assume homogeneous material properties, thereby neglecting any material heterogeneities. Clearly, this approach is based on a quite strong simplification, and potentially entails inadequate simulation results, as demonstrated in (Dejaco *et al.*, 2012). Furthermore, simplified empirical laws can be used for relating the distribution of gray values resulting from CT scanning to a corresponding distribution of material properties. Unarguably, this approach may work well for a certain material, whereas it may be completely wrong for another material.

This chapter is however not focusing on the standard methods mentioned above – respective review articles and textbooks can be found straightforwardly in the open literature. Instead, the remainder of the chapter presents a selection of alternative and complementing approaches, which could further improve the applicability of mathematical models in clinical practice.

Homogenization of Mechanical Properties Based on Continuum Micromechanics

As described briefly further below, continuum micromechanics is a theoretical concept particularly well suited for bone tissue and also bone replacement materials. Within the framework of continuum micromechanics, a material is considered to be macro-homogeneous, but micro-heterogeneous. If the characteristic length of such micro-heterogeneities, termed d , is significantly smaller than the characteristic length of a volume element containing them, termed l_{RVE} , this volume element is referred to as *representative volume element* (RVE). Thereby, “significantly smaller” is not precisely defined, but it has been shown that l_{RVE} must be at least 2–3 times larger than d (Drugan and Willis, 1996). Furthermore, l_{RVE} must be significantly smaller than the characteristic lengths of the geometry making up the structure composed of the material defined by the RVE, termed L , and of the loading acting onto this structure, termed P . Practically, this requirement is satisfyingly fulfilled if L and P are at least 5–10 times larger than l_{RVE} (Kohlhauser and Hellmich, 2013). Typically, the microstructure of the material contained in an RVE is way too complex for describing it in detail. Instead, so-called material phases, which are assumingly homogeneous (in an approximative sense), are introduced. The material phases are chosen such that they exhibit known physical properties, such as volume fractions or mechanical properties, and a variety of different phase morphologies can be established, thereby allowing for considering different phase shapes, or interactions between the considered material phases.

If separation of scales is fulfilled, as described above, continuum micromechanics provides mathematical tools for scaling mechanical properties known on the scale of individual material phases up to scale of the macroscopic material, based on combining Eshelby's matrix-inclusion problem (Eshelby, 1957) with stress and strain volume averaging laws. In this chapter, all mathematical details related to deriving the related homogenization schemes are omitted, and the interested reader is referred to pertinent literature (Hill, 1963, 1965a,b; Suquet, 1997; Zaoui, 2002; Dormieux, 2005).

The very basis for using continuum micromechanics models in the field of bone tissue engineering was laid by developing respective models for bone tissue. First attempts focused on homogenizing bone stiffness (Hellmich and Ulm, 2002; Fritsch and Hellmich, 2007; Vass *et al.*, 2018), based on which subsequently strength homogenization approaches were developed (Fritsch *et al.*, 2009; Morin *et al.*, 2017). Based on very similar modeling considerations, micromechanics models were developed for bone tissue engineering materials, comprising hydroxyapatite-based biomaterials in general (Fritsch *et al.*, 2010) or very specific, hydroxyapatite-based granules applied in dental engineering (Scheiner *et al.*, 2016a,b). Furthermore, it could be demonstrated how biomaterials can be modeled in a poromicromechanical framework, thereby allowing to study the influence of the respectively chosen poromechanical configuration on the macroscopic strength estimates (Fritsch *et al.*, 2013).

Clearly, this method can be applied and adapted to any hierarchically organized material fulfilling the separation-of-scales-requirement. This is particularly true for *hard* materials, for which the existing theoretical concepts, see also the references above, can be straightforwardly considered. For *soft* tissues, the equations describing the constitutive behavior of the materials must be reasonably extended and adapted, owing to the potentially arising large deformations which are not encountered in hard tissues.

Bone Tissue Systems Biology Approaches

Keeping in mind that bone replacement materials serve the purpose of allowing for or stimulating bone regeneration in the vicinity of the respective tissue engineering scaffold, it would be a desirable goal to actually predict how well a specific material or a specific structure would perform before inserting it into the patient's body. To that end, understanding the process of bone regeneration is key.

Bone regeneration is a complicated biological process (Petite *et al.*, 2000; Lieberman and Friedlaender, 2005). Essentially, the growth of new bone tissue in the pore spaces of bone tissue engineering scaffolds comprises numerous biochemically and mechanically stimulated mechanisms. First, they cause addition of bone tissue by mononuclear cells called osteoblasts, deriving from mesenchymal stem cells. In more detail, osteoblasts lay down osteoid to fill this cavity, a substance consisting mainly of collagen type I. Over time, osteoid gets mineralized, with the bone mineral mainly consisting of carbonated hydroxyapatite. Since the greater part of bone mineral is formed very fast (within a few days), osteoblasts are often, for simplicity, referred to as bone-forming cells, without explicitly mentioning the intermediate step of osteoid secretion. Hence, initiation of bone regeneration requires the attraction of such stem cells to the pore spaces of the implanted scaffold, and creation of a milieu which facilitates the required differentiation processes.

Once the scaffold is (at least partly) covered with bone tissue, also remodeling events take place, implying that the bone tissue is removed by multinuclear cells called osteoclasts, deriving from hematopoietic stem cells. More precisely, osteoclasts attach themselves to the bone surface, thereby creating an acidic environment in order to dissolve the bone matrix, thus leaving behind a resorption cavity. This cavity is subsequently filled with new bone tissue by osteoblasts. Moreover, osteocytes, a third cell type found in bone, has been identified as bone remodeling "conductor". In particular, osteocytes are former osteoblasts that have been "buried" in newly secreted osteoid. Osteocytes are the most abundant cell type in bone tissue, and they are considered to be capable of sensing changes in their environment, particularly concerning the mechanical loading. There is ample evidence that osteocytes transduce these changes into biochemical signals, which, in turn, lead to corresponding changes of cellular activities in the bone microenvironment.

As for the exact biochemical regulatory pathways, the discovery of the receptor activator of nuclear factor kappa beta (RANK) and its ligand (RANKL) allowed for understanding the interplay between osteoblasts and osteoclasts. Namely, binding of RANKL, which is produced by both osteoblasts and osteocytes, to RANK, which is a transmembrane protein found on osteoclasts, is required for differentiation of osteoclasts. Furthermore, osteoprotegerin (OPG), a protein which is produced by osteoblasts, is a so-called decoy receptor, as it also binds to RANKL and thereby prevents osteoclastogenesis. Furthermore, the parathyroid hormone (PTH) influences the RANK-RANKL-OPG pathway, through promoting the production of RANKL and inhibiting the production of OPG. Transforming growth factor beta (TGF-beta), in turn, promotes the differentiation of osteoblast progenitor cells, inhibits the differentiation of osteoblast precursor cells, and promotes the apoptosis of osteoclasts. The list of factors contributing to the regulation of the bone cells could be easily extended by further proteins and hormones (such as nitric oxide, prostaglandins, vitamin D, corticosteroids, interleukins, calcitonin, or the Wnt beta-catenin pathway, just to mention a few), see (Robling *et al.*, 2006; Jacobs *et al.*, 2010; Bonewald, 2011) for respective review articles.

Mechanical excitation of bone cell activities is a heavily debated field, and several hypotheses have been brought forth over the years, including direct stretching of the cell-surrounding bone matrix, the hydrostatic pressure to which the cells are exposed, the fluid flow in the bone pore spaces, or microcracks emerging as result of local overloading (Robling *et al.*, 2006; Jacobs *et al.*, 2010). Also the exact consequences of changing mechanical loading, in terms of the mechanotransductive response, are not completely resolved. Experimentally confirmed hypotheses include the increase of osteoblast proliferation due to increased mechanical loading (with respect to "normal" loading conditions), and the increase of RANKL production due to decreased mechanical loading.

The above sketched regulatory mechanisms of bone formation and resorption have not yet been considered at all in the context of computational models of bone regeneration. The addition of bone tissue is usually considered based on simple laws, mostly involving scalar representatives of the location-dependent mechanical loading as functional argument, see e.g., (Adachi *et al.*, 2006), while biological details are completely neglected. The latter deficit could be eradicated by integrating into the structural simulations of bone tissue engineering scaffold systems biology-based bone models of the bone metabolism, see e.g., (Lemaire *et al.*, 2004; Pivonka *et al.*, 2008, 2010; Graham *et al.*, 2013; Scheiner *et al.*, 2013; Pastrama *et al.*, 2018). These models allow for consideration of cell populations, different developmental stages along the cell lineages, and regulation of cell differentiation, proliferation, and apoptosis processes by biochemical factors. The fundamental mathematical tools for such models are (ordinary or partial) differential equations. For example, in (Pivonka *et al.*, 2008, 2010), a set of three coupled ordinary differential equations is proposed, each of which represents the evolution a specific cell population. Solving these equations (which is and usually has to be done numerically, by means of approximating algorithms) gives then access to the developments of the considered cell populations over time. In some references (Scheiner *et al.*, 2013; Pastrama *et al.*, 2018), bone systems biology models are furthermore coupled with a bone micromechanics model for estimating the local mechanical stimulus perceived at the cell level, in order to include a physically meaningful argument for biomechanical regulation of the bone cell activities.

Utilization of Micromechanics for Quantification of Mechanobiological Stimuli

Let us tie in with the above-raised argument concerning the utilization of micromechanical models for quantifying the mechanical stimulus acting onto the cells driving bone regeneration. It could be shown that the hydrostatic pore pressures in the pore spaces of bone can be reliably predicted (Scheiner *et al.*, 2016c); fluid flow in the canaliculi and lacunae, occurring in response to macroscopic mechanical loading, can be estimated by downscaling related pressure gradients to the relevant pore spaces, see e.g., (Estermann and Scheiner, 2018); and microcracking can be introduced by taking into account suitable failure criteria defining the

onset of cracking events in the bone matrix (Fritsch *et al.*, 2009; Morin *et al.*, 2017). Furthermore, other mechanisms hypothesized to trigger bone cell activities, such as piezoelectric excitation (Ahn and Grodzinsky, 2009) can be also covered by multi-scale, micromechanics-inspired modeling approaches (Dunn and Taya, 1993).

X-Ray Physics-Based Analysis of CT Data

In biomedical practice, studying tissues or whole organs by means of an X-ray-based method is a common standard. When aiming at revealing the three-dimensionally distributed geometry and composition of such a tissue, computed tomography (CT) is usually applied. In order to process the information collected by means of CT scans properly, revisiting the theoretical foundation is crucial.

During a CT scan, X-rays are sent through the studied object, and the reduction of the X-ray intensity upon passing through the object, referred to as attenuation, is measured. By varying the direction of the X-ray as well as the position of the source of the X-ray, a comprehensive set of attenuation data is gathered. The Radon transform (Radon, 1917) is then utilized, in order to process the attenuation behavior in terms of the three-dimensional distribution of attenuation coefficients. Usually, the attenuation coefficients are expressed in terms of gray values which are proportional to the attenuation coefficients. Depending on the setting of the tomograph, corresponding resolutions can be achieved, typically in the range of a few micrometers. Thus, the studied object is then reflected in the CT data as an assembly of voxels (which are cubic domains whose side length is defined via the resolution); and each voxel is characterized by a constant gray value, representing the average attenuation coefficient within this voxel.

Using the CT data as basis for reconstructing the exact shape and geometry of the scanned objects, e.g., for building corresponding numerical models, is an often applied strategy. However, it has been shown in the past years that additionally, information concerning the composition of the material making up individual voxels can be extracted. To that end, the proportionality of the recorded attenuation coefficients to the voxel density is utilized. Taking into consideration that the voxel density, in turn, is proportional to the volume fractions of the materials contained within the voxels, the composition of the voxels can be straightforwardly deduced. The resulting field of material compositions can, in further consequence, be fed into micro-mechanical homogenization schemes, in order to obtain also a field of mechanical properties, discussed in the previous section, see e.g., (Hellmich *et al.*, 2008; Scheiner *et al.*, 2009; Dejaco *et al.*, 2012; Czenek *et al.*, 2014; Szlczak *et al.*, 2019).

For the sake of demonstration, Fig. 2(A) shows the gray value distribution in a cross-section of a granular, hydroxyapatite-based biomaterial obtained by means of micro-CT scanning. Analyzing the distribution of gray values as described above gives then access to the corresponding distribution of volume fractions of the constituents, i.e., of hydroxyapatite and of air pores. Considering the micro-morphology of the studied material suggests employing Mori-Tanaka-type stiffness homogenization. Feeding the resulting distribution of elastic constants into a structural model allows for simulation of the mechanical behavior of one of these granules when subjected to physiologically relevant mechanical loading, such as uniaxial compression, see Fig. 2(B) and (C). Comparison of these two images clearly underpins the importance of taking into account the heterogeneous distribution of mechanical properties, as was done in the simulation behind Fig. 2(B), instead of simply assuming, for simplicity average mechanical properties which are constant for all voxels, see Fig. 2(C).

Further Modeling Strategies

The above-presented modeling strategies appear to be a valuable set of computational tools which should (at least) be considered when facing the task of developing a model for some kind of tissue engineering application. However, the story does certainly not end at this point. Hence, this section is devoted to presenting further methods which have proved useful.

Fig. 2 (A) Gray value distribution in a cross-section of a granular, hydroxyapatite-based biomaterial, obtained by means of micro-CT scanning; distribution of the deviatoric stress norms resulting from FE simulations considering uniaxial compression, with load initiation occurring on the lateral sides of the granule, for (B) heterogeneous and (C) homogeneous stiffness properties. Reprinted from Dejaco, A., Komlev, V.S., Jaroszewicz, J., Swieszkowski, W., Hellmich, C., 2012. Micro CT-based multiscale elasticity of double-porous (pre-cracked) hydroxyapatite granules for regenerative medicine. *Journal of Biomechanics* 45, 1068–1075.

Two mechanisms are of particular interest in tissue engineering, in order to make sure that the inserted material blends in well into the physiological environment: dissolution of the scaffold and growth of new biological tissue. In order to anticipate how well a particular tissue engineering material performs, mathematical models were developed. e.g., a set of simple equations was introduced in (Chen *et al.*, 2011), essentially comprising degradation kinetics laws of the polymer under investigation, a hydrolysis law, and Fick's second law of diffusion. An extended diffusion-convection-reaction modeling framework was proposed in (Akalp *et al.*, 2016), extended by constitutive laws of the studied hydrogel, and some additional laws for defining the underlying material parameters. A somewhat simplified approach was taken in (Byrne *et al.*, 2007), where a fixed dissolution rate governs the temporal change of the studied scaffold within a large-scale numerical model. A similar approach was pursued in (Nava *et al.*, 2013), however for the growth of newly formed tissue in a bioreactor environment. The growth rate was considered to be dependent on the shear stress to which the particular location on the scaffold was subjected, and on the oxygen concentration. A set of equations reflecting the detailed stoichiometry of dissolution was presented in (Sanz-Herrera *et al.*, 2018), showing that dissolution (and also growth) do not need to rely on phenomenological equations but can also be modeled in minute detail.

Molecular dynamics is a modeling concept which has turned out to be well suited for assessing the biocompatibility of tissue engineering materials, see e.g., (Katti *et al.*, 2008; Sarmadi *et al.*, 2017). Molecular dynamics can also be employed for studying the absorption/desorption behavior of relevant factors onto the biomaterial surface (Huang *et al.*, 2018), or the interaction of biomaterials with its environment (Gopalakrishnan and Subramanian, 2011). Furthermore, the mechanical properties of composites on very small length scales has been studied by molecular dynamics simulations, see e.g., (Ebrahimi *et al.*, 2013).

In order to make the production process of biomaterials as predictable as possible, mathematical models have been used. Examples range from very basic computer-aided design (which is not necessarily mathematical modeling per se, but which can be extended by models for optimizing the eventually arising structure) (Mironov *et al.*, 2003) to more complicated models of the electrospinning process, comprising transport laws; mass, momentum, and charge balance equations; and a comprehensive set of constitutive equations (Wan *et al.*, 2004).

Assessing the processes governing the development of biological tissues in their physiological environments is very difficult (if not impossible). As a remedy, bioreactors are used. Bioreactors aim at creating a realistic replica of the physiological environment, and allow for inserting testing and monitoring equipment, improving the knowledge as to the exact conditions around the tissue under examination. Mathematical models were proposed for the sake of, firstly, reproducing the processes inside the bioreactor, and of, secondly, optimizing the scaffold's performance (Chung *et al.*, 2007; Couet and Mantovani, 2012). Furthermore, mathematical models were developed for optimizing the bioreactors themselves as well (Hidalgo-Bastida *et al.*, 2012).

Conclusions and Outlook

The mathematical modeling strategies in this contribution are supposed to provide an outlook as to how computer simulations may support patient-specific design of tissue engineering scaffolds may look like in the future. It goes without saying that the interested reader should not restrict her- or himself to the presented methods and references, but should probably consider this chapter as basis for looking deeper into the vast realm of mathematical modeling in biomedical engineering in general, and in tissue engineering in particular.

In order to make predictive computer simulations actually applicable in clinical practice, additional efforts are certainly necessary and will keep researchers busy for years to come. These efforts should probably focus, on the one hand, on improving the physical and biological foundation of the models, and on improving the current state of the art in the field, from a theoretical point of view. On the other hand, establishing mathematical models as credible tool among medical doctors is a second grand challenge. To that end, particular emphasis should be laid on experimental and clinical validation of the models, and on developing simulation tools such that they are eventually quickly applicable by non-experts as well. If these challenges are successfully met, chances are good that mathematical modeling will become a standard technology in tissue engineering in the foreseeable future.

Introduction

The term biomaterial includes all materials or systems proposed for clinical applications to replace part of a living system or to function in intimate contact with living tissues. Materials science researchers and engineers are exploring this complex domain, as it requires consideration of biocompatibility, i.e., acceptance of the artificial implant by the surrounding tissues and, in the frame of Regenerative Medicine, assessment on bioactivity, bio-reabsorbability and ability to be integrated and remodeled. Such a research field requires interdisciplinary approaches and robust knowledge of chemistry, biology and mechanics, in order to cope with the complex chemical composition, multiscale structure and biological functions of the organ to be replaced/regenerated. In fact, after decades of attempts to develop biomaterials able to effectively regenerate tissues/organs, most of them failed in their task and today the need of a radically new approach is commonly recognized. In this scenario, the chapter describes new frontiers in biomaterial development, fed by novel nature-inspired approaches, and able to circumvent the limitations of the current ceramic technology. Thus it will be illustrated how the biomineralization process, by which nature builds innumerable biologic structures, could be used to obtain scaffolds for regeneration of bone and also complex anatomical regions such as the osteochondral and periodontal tissues. We will show recent developments for load-bearing scaffolds fabrication by using a revolutionary biomorphic transformation process, able to convert a natural hierarchically organized structure in fully ceramic and bioactive devices retaining the original 3-D multiscale structure and the unique damage tolerant performance. Finally, it will be shown how such new bio-devices can be powered by functionalization with magnetic doping and/or nanoparticles, to obtain on-demand activation of bio-functionalities. Particularly, the recent development of a biocompatible, bioactive superparamagnetic apatite is described, as a tool very promising to apply novel safer therapies in nanomedicine and to boost the endogenous potential of debilitated patients.

The “Biomimetic Approach”

The term biomimicry, entered in the scientific language in 1982, refers to a “new science that studies nature’s models and then imitates or takes inspiration from natural designs and processes to solve human problems”. Such a new tendency in material science suggests looking to Nature as a “Model and Mentor” and emphasizes sustainability as one of the main objective (Benyus, 1997). Indeed, materials found in nature combine many inspiring properties such as sophistication, miniaturization, hierarchical organizations, hybridation, resistance and adaptability. Differently, using a classic design approach, some properties turn out to be exclusive, such as for instance strength and toughness where strong materials are brittle and tough materials are relatively weak. However, natural materials with complex and hierarchical morphology and structure that span from nano- to macro-scales are both strong and tough. Generally, natural materials utilize very basic chemical components but such molecular building blocks are organized into complex architectures that give rise to exceptional mechanical properties: bone, nacre, teeth and woods are great examples of damage tolerant materials (Wegst *et al.*, 2014). The exceptional resistance to fracture of bone is due to complex deformation and toughening mechanisms that operate at different size scales i.e., from the nanoscale structure of protein molecules to macroscopic hierarchic architectures (Launey *et al.*, 2010). Recently, one of the most successful approach in designing and developing biomaterials for regenerative medicine is the biomimetic approach that is the effort to mimic the whole characteristics of the native tissue/organ. More specifically, the idea embodied in the concept of “biomimetics” is that the physico-chemical and morphological features of implanted biomaterials must be, by themselves, signals able to stimulate cell chemotaxis and colonization by autologous cells that work to remodel the original tissue/organ. In this way, the human body can be considered as a natural bioreactor able to guide appropriate tissue regeneration starting from a biomimetic scaffold without artificial addition of cells or other biological factors but simply recalling autologous cells and preserving the physiologic equilibrium and homeostasis, thanks to the reproduction of biologic environmental cues. In the practice of tissue/organ regeneration, the use of scaffolds is required particularly when it comes to regenerate large bone defects, since cells need a bioactive and bioresorbable bridge to start the remodeling cascade leading to a complete regeneration of the missing tissue and avoiding bad clinical outcomes such as non-union phenomena.

To this aim, nanocrystalline calcium phosphates (CaPs) exhibiting multiple ionic substitutions (e.g., Mg^{2+} , CO_3^{2-} , Sr^{2+}) are well reputed as the best in class materials for bone regeneration and have been extensively investigated in the past decade. Unlike stoichiometric hydroxyapatite (HA) that is only composed of Ca, PO_4 and OH, biological HA incorporates in its lattice several ions present in the physiological environment through ionic substitution or interstitial adsorption (see Fig. 1). This incorporation of doping ions is a dynamic process, changing in function of the age and physiological condition of the individuals; it modifies

Fig. 1 Scheme of the synthesis and composition of a biomimetic hydroxyapatite.

several structural and physico-chemical HA parameters, such as reticular constant, crystal's morphology and size, crystallinity, thermal stability and solubility and thus affects decisively the phase bioactivity (Sprio *et al.*, 2008; Iafisco *et al.*, 2014a).

Among doping ions, CO_3^{2-} ions can occupy two different sites of the apatite lattice. B-substitution occurs at the PO_4^{3-} site, influencing the surface polarity and thus improving the osteoblasts adhesion and is typical of young and immature bones; conversely, carbonation in site A refers to partial substitution of OH^- , which increases the stability of mineral phase and in fact, it is more typical of mature bone tissue. Incorporation of Mg^{2+} ions influences the HA bioavailability, decreasing the crystallinity and promoting the nucleation and new apatite nuclei. Substitution of Calcium with Sr^{2+} ions has been largely studied thanks to its ability to restore the bone turnover balance, this is important for the treatment of osteoporotic bone fractures. Some positive results on the efficacy of local release of strontium were obtained in recent studies based on titanium implants functionalized with strontium or coated with strontium-substituted HA. (Li *et al.*, 2010). Combined substitution of Calcium with Fe^{2+} and Fe^{3+} ions were recently studied to endow HA with unique superparamagnetic ability and generate a new biocompatible and bio-resorbable FeHA nanophase, characterized by multiple functionality and high safety (Sprio *et al.*, 2008; Tampieri *et al.*, 2012). In particular, FeHA exhibits high magnetization under external static magnetic fields, in spite of very low amounts of secondary iron oxides, so that it can also exhibit excellent biocompatibility and bioresorbability (Panseri *et al.*, 2012; Panseri *et al.*, 2016).

Such bioactive ceramics are chemically unstable in physiologic environment, they are able to exchange bioactive ions with the surrounding environment and instruct cells to specific tasks, so that they might be considered as "inorganic metabolic phases". The production of biomimetic, bioactive CaPs has been carried out using several methods (Sprio *et al.*, 2008; Iafisco *et al.*, 2014b), but the final product is a fine powder that has to be subsequently treated with forming and sintering techniques to obtain 3-D porous devices. In fact, the scaffold should exhibit interconnected, multiscale porosity: large pores (200–400 μm) to ensure cell colonization, and a diffuse nano, micro-porosity for exchange of nutrients and waste products. Moreover, such features have to be associated with adequate mechanical performance withstanding physiological mechanical forces. Nevertheless, the conventional approaches for material processing do not allow accurate control of crystal and compositional changes, particularly during the high temperature consolidation process, so that irreversible crystal growth and alteration of bioactive chemical compositions and crystal structures occur, leading to reduction of the material's bioactivity and cell-instructive ability (Tampieri *et al.*, 2003). The fabrication of bio-functional 3-D ceramics retaining bioactive chemistry and nanostructure poses significant challenges. In fact, the current processing to consolidate inorganic materials with relevant mechanical performance requires the use of sintering treatments, which normally degrade the bio-active metastable phases and, in case of HA, induce the expulsion of doping ions and the re-crystallization process.

In attempting to preserve the relevant physico-chemical and biological properties of synthetic bioactive HA, when obtained as 3-D scaffolds, previous studies investigated different nature-inspired technologies either with a bottom-up or with a top-down approach. In the first case, the application of a biomineralization process represents the translation of the natural nano-technological process responsible for the natural bone and tooth formation, where a bio-organic macromolecule assembles into complex 3-D architecture and drive the heterogeneous nucleation of apatite nano-phase. When carried out by laboratory procedures, the mineralization of artificially assembled natural polymers generates hybrid-composites endowed with high similarity with natural mineralized tissue and superior biological performances. Such a process could be reproduced by exploiting the ability of collagen molecules to assemble into fibrils and thicker fibers by pH variation, that contemporary induces HA nuclei formation at the interface, at body temperature (Fig. 2). The biomineralization process activates multi-scale control mechanisms, thanks to the information stored in the complex structure of collagen macromolecule; particularly, chemical, structural and morphological mechanisms are activated and control the nanosize and crystal orientation of the nucleated mineral phase which can maintain

Fig. 2 (left) Scheme of the biomineralization collagen fibers; (right) Scanning electron microscopy and X-ray diffraction of biomineralized collagen fibers.

high instability level and capability of dynamic ion exchange. In particular, during Collagen fibers' self-assembly, the molecules of tropocollagen leave a regular array of 40-nm gaps within each periodic unit and such zones are called hole zones. The mineral phase of hard tissues preferentially nucleates exactly in these sites, and grow under the control exerted by the interaction with non-collagenous acidic macromolecules present in the hole zones and linking carboxylate groups and Ca^{2+} ions of the mineral phase. Specifically, the growth of the apatite-like nuclei is confined to very thin lamellae (45 nm in length, 20 nm in width and $\sim 2\text{--}3$ nm in thickness) with specific crystal orientation, as revealed by XRD analysis in flat chamber (see Fig. 2). A reflection very narrow and enhanced in intensity corresponding to the [002] plane refers to a preferential growth of the hexagonal apatite lattice along its c axis, thus favouring exposure of the ab face. Previous studies reported that proteins such as osteocalcin and osteopontin, present in the extracellular matrix and active in the bone formation and remodeling process, are chemically affine with the ab plane of hydroxyapatite (Mann, 2001). Therefore, it appears that biomineralization process could generate hybrid HA/Collagen constructs mimicking physico-chemical features of the immature bone tissue from the macro to the sub-nano scale, as instructive guides for bone regeneration.

The obtained hybrid gels can be treated by freeze-drying or freeze casting, thus generating scaffolds with high compositional and structural similarity with natural bony tissue and also graded structures resembling complex anatomical regions like the osteochondral and periodontal ones (Sprio *et al.*, 2014). The final product of such a process is a fibrous, porous construct able to deform elastically in liquid media, thus showing remarkable adaptability to any bone tissue defects but at the same time, inability to retain its original volume under compressive forces so that its use is so far limited to non load-bearing defects. Biomineralization is among the first attempts to exploit the unique features of biologic processes to fabricate scaffolds retaining physicochemical and architectural features typical of native tissues (Sprio *et al.*, 2016; Murray *et al.*, 2012). In this respect, the following paragraphs illustrate some examples of biomimetic hybrid scaffolds addressed to regeneration of multifunctional anatomical regions such as the articular joint and the periodontium, i.e., scaffolds prepared in graded fashion to regenerate simultaneously different tissues characterized by increasing mineralization extent.

Hybrid Scaffolds for the Regeneration of Multifunctional Anatomical Regions

Biomimetic Scaffolds for Osteochondral Regeneration

Osteoarthritis (OA), the most common form of arthritis, is a serious disease affecting the joints and is the fastest growing cause of disability worldwide (Vos *et al.*, 2012; Kingsbury *et al.*, 2014). Recent evidence suggests that we are moving towards a worldwide OA epidemic, particularly in Europe, where OA is estimated to affect >40 million people, (Buckwalter *et al.*, 1993) with a prevalence directly associated with ageing (Hutmacher, 2000; Hutmacher *et al.*, 2000; Martin *et al.*, 2000; Barbour *et al.*, 2017; Ethgen and Reginster, 2004; Hootman *et al.*, 2016; Henderson *et al.*, 2007).

The regeneration of osteoarticular regions affected by OA is thus one of the most demanding clinical needs nowadays and a target of high impact for biomaterials science and regenerative medicine. So far, most of attempts to regenerate osteochondral tissue in patients affected by OA or osteochondral defects have not resulted in a stable and reproducible restoration of joint function (Knutsen *et al.*, 2004; Kraeutler *et al.*, 2018; Cao *et al.*, 2003). An issue hampering the development of scaffold for osteochondral regeneration is the need to treat simultaneously the articular cartilage surface and the underlying subchondral bone. Even if various therapeutic approaches have been developed to treat osteochondral defects, none of them has proved yet to ensure long-lasting regeneration. One of the most promising strategies consists in the generation of hybrid scaffolds with graded composition and structure, obtained by the combination of distinct but integrated layers corresponding to the cartilage and bone regions (Chen *et al.*, 2011; Panseri *et al.*, 2012; Tampieri *et al.*, 2011; Sprio *et al.*, 2018). Among these approaches, the biomineralization process is particularly interesting, as it is able to activate a complex sequence of phenomena occurring at the molecular level and guiding the nucleation of nano-nuclei of CaP phases on self-assembling collagen fibers mimicking the process occurring *in vivo*. The high compositional and structural mimicry of the hybrids with the natural tissues is the basis of excellent bioactivity and bioresorbability, which can occur through cell and enzymatic activity. Very important, favouring the natural metabolic processes, the use of hybrid biomimetic devices can prevent any adverse effects related to foreign body reactions and this is very important particularly for aged patients, for which tissue regeneration is somewhat hampered by reduced endogenous potential.

Fig. 3 (up) Sketch about the synthesis of hybrid device for osteochondral defect and (down) histology analysis of in vivo implant of hybrid osteochondral scaffold at six months of follow-up in sheep showing well-oriented collagen fibers, formation of type II collagen and columnar orientation of chondrocytes.

The biomineralization process rises interest also due to its flexibility in achieving hybrid constructs with different compositions, fiber orientation and texture, porosity extent and stiffness (Sprio *et al.*, 2008), acting on few key parameters during synthesis, crosslinking and freeze-drying process in a relatively simple fashion. A previous study showed how the biomineralization process was directed to obtain scaffolds with graded composition, porosity and morphology, in order to reproduce different histological areas in the osteochondral tissue. Therefore, by simply varying the degree of mineralization and the alignment of collagen fibers different hydrogels with specifically designed features were engineered into three-layered devices reproducing the sub-chondral bone (mineralization extent = 60–70 wt%), mineralized cartilage (mineralization extent = 30–40 wt%), and the hyaline cartilage (mineralization extent = 0 wt%) as Fig. 3 shows (Tampieri *et al.*, 2003). Freeze drying processes can be applied to guide the water sublimation and the fiber alignment thus generating dried fibrous constructs with tailored and oriented porosity extent. The non-mineralized collagen layer reproduced the typical columnar-like structure of the articular cartilage, with the fibers converging towards the external surface and form horizontal flat ribbons, thus resembling the morphology of the *lamina splendens* (Sprio *et al.*, 2008; Kon *et al.*, 2010). Bio-hybrid graded composites have demonstrated enhanced cell proliferation with very spread cell morphology, as well as high osteoinductivity and regenerative potential. In fact, they were able to differentially support cartilage and bone tissue formation in both the cartilaginous and bony layers, as demonstrated by comparative in vivo study carried out on adult sheep, where hydroxyapatite/collagen graded composites have been implanted on femoral condyles (Haumschild and Haumschild, 2009). In particular, histological evaluation showed the formation of new hyaline-like tissue and good integration of scaffolds with host cartilage, with a strong proteoglycan staining and columnar rearrangement of chondrocytes, and an underlying well-ordered sub-chondral trabecular bone (Fig. 3).

Biomimetic Scaffolds to Treat Periodontal Diseases

Periodontitis is an inflammatory disease affecting the tooth, it is extremely widespread worldwide and has a prevalence that is similar to cardiovascular disease and diabetes (Williams *et al.*, 2008; Dye, 2012), estimated as 25%–47% (Hajishengallis, 2010). Periodontitis is widespread, particularly among the elderly, attributed to accumulated exposure to different type of foods, medications and physical environments but, on the basis of recent studies, it is also related to a change in susceptibility with ageing (Bartold *et al.*, 2000). Severe periodontitis is characterized by tissue resorption involving both the alveolar bone and cementum, which provokes the tooth loss. The current approaches for the treatment of periodontal diseases are mostly based on preservative and conservative approaches. However ever-increasing attention has been focused on regenerative therapies, rather than resective surgery, to establish guided periodontal regeneration which, to date, is considered the only successful therapeutic approach to stimulate the activity of multiple cell lineages active in the oral environment (e.g., osteoblasts, cementoblasts, dentinoblasts, endothelial (Linde and Goldberg, 1993; Maeda *et al.*, 2014; Bodineau *et al.*, 2009)) and to promote the formation of new dental tissues with appropriate texture and biomechanical competence. The oral environment is particularly prone to infections and in this respect, it was observed that aged people have higher levels of some Gram-negative bacilli, such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, and *Enterobacter*, as compared with young individuals that could affect the incidence of periodontitis in the elderly (Sprio *et al.*, 2018).

Giving the great complexity of the cell interactions and cross-talk in dental tissues, it is very hard to contrive effective regenerative approaches, even if a scaffold is adopted. In this respect, the use of biomimetic hybrid scaffolds can be promising since they can recapitulate relevant features of native tissues, and possibly instruct the cells only by virtue of physicochemical, topological and structural properties (Lee *et al.*, 2014). To this purpose, the biomineralization process was applied to fabricate hybrid graded scaffolds recapitulating the physico-chemical, morphological and structural features of the different periodontal tissues (see Fig. 4). The strategy was based on the creation of a multi-layer construct with different region-specific pore/channel sizes and material composition (Sprio *et al.*, 2018; Bortolomai *et al.*, 2019), related to the periodontal ligament, the cementum, and the alveolar bone.

The bottom layer mimicking alveolar bone has been obtained as a hybrid porous construct made of Mg, CO₃-doped hydroxyapatite nano-crystals nucleated on self-assembling collagen fibrils and retaining very low, bone-like, crystallinity degree. To enhance cell differentiation, the mineral phase was partially doped with Fe²⁺/Fe³⁺ ions, as a tool providing magnetic signals to activate osteoblast cells. The middle layer mimicking periodontal ligament (PDL) is composed of a collagen membrane obtained by tape-casting technique matched with an air-drying process under environmental condition. This process permitted to maintain

Fig. 4 Bio-inspired approach to fabricate biomimetic periodontal scaffolds.

Fig. 5 Live&Dead of cells into different periodontal regions.

a thin and highly porous central area, relevant to promote extensive vascularization and diffusion of nutrients to the cementum layer. 1,4-Butanediol diglycidyl ether (BDDGE) was selected as a cross-linking agent to increase the stability of PDL and to promote the formation of bridges through covalent links between the collagen fibers (Krishnakumar *et al.*, 2018; Sandri *et al.*, 2016; Goncalves *et al.*, 2005). The top layer mimicking the cementum was composed of ion doped hydroxyapatite mixed with cellulose acetate (CA), and deposited by electrospinning to obtain a fibrous structure with mineralization degree $\sim 50\%$, able to form bundles around the fibers of the PDL, and with high density of tight pores, all features relevant for anchoring the tooth to its alveolus and for entrapping cementoblasts (Ho *et al.*, 2009; Maredziak *et al.*, 2016). Thanks to these unique structural properties and biomimetic composition, the scaffold showed excellent cytocompatibility and viability as Fig. 5 highlights.

Emerging Technologies for Regeneration of Load-Bearing Segmental Bones: Biomorphic Transformation of Natural Structures

The hybrid scaffolds obtained by biomineralization process are fibrous, porous and able to deform elastically in liquid media, thus showing remarkable adaptability to tissue defects, and particularly effective in regeneration of complex anatomical region but, at the same time, unable to retain its original volume under compressive forces. To design scaffolds with mechanical strength enabling application in critical size bone defects, bioactive ceramic powders have been used in association with biocompatible and bio-erodible polymers. The as-obtained printable pastes have been also used for the fabrication of 3-D porous scaffolds by additive manufacturing techniques (Rezwan *et al.*, 2006). However, besides the scarce compositional and mechanical similarity with bone tissue, polymer-based scaffolds often exhibit non-enzymatic dissolution profiles for which acidic and harmful by-products can be released, altering cell metabolism and vitality thus jeopardizing tissue healing (Liu *et al.*, 2006). Furthermore, the regeneration of large bone defects is much more demanding than a simple bone cavity or a non-load bearing bony region. In fact, in combination with bioactive composition and porous morphology, the mechanical properties play a key role, because of the need to withstand multi-modal mechanical stimuli whereas stimulating cells to produce new bone tissue. The bone ability to cope with mechanical forces is strongly related to its complex hierarchical architecture, as occurs in the majority of bio-structures, giving unusual and superior performance in comparison with any artificial materials (Wongmaneerung *et al.*, 2009; Roulland *et al.*, 2005; Qian *et al.*, 2013; Cazalbou *et al.*, 2005). Such peculiar structure allows an efficient distribution of the mechanical loads from the macroscale down to the smallest trabeculae, where strain-sensing mechanisms exhibited by the osteocyte cells can take place and activate the permanent bone remodeling process (Iafisco *et al.*, 2014a; Limonov and Richard, 2016; Sprio *et al.*, 2008). Unfortunately, the fabrication of functional 3-D inorganic materials retaining nanostructure poses significant challenges and activate degradation phenomena (Wongmaneerung *et al.*, 2009; Roulland *et al.*, 2005; Limonov and Richard, 2016). A very relevant case study is given by nanocrystalline calcium phosphates (CaPs) exhibiting multiple ionic substitutions (e.g., Mg^{2+} , CO_3^{2-} , and Sr^{2+}), which are well known as the elective phases to develop scaffolds for bone regeneration (Rey *et al.*, 1989; Dahl *et al.*, 2001; Bertinetti *et al.*, 2009). Although, when in the form of nano-powders, the synthesis of such bioactive ceramics is not a critical task (Iafisco *et al.*, 2014a; Sprio *et al.*, 2008), its development in form of 3-D scaffolds, endowed with adequate mechanical performance, is a challenge that the scientific community is intensively facing. In fact, current fabrication methods do not allow accurate control of crystal and compositional changes, particularly during the consolidation process, where irreversible crystal growth and chemical stabilization occurs, reducing the scaffold bioactivity (Tampieri *et al.*, 2011). Furthermore, the current processes for the development

Fig. 6 Scheme of (left) single steps of synthesis and (right) the multi-scale structure of wood and bone tissue.

of inorganic scaffold do not allow the generation of complex organized hierarchical structure, mimicking the natural ones (Schumacher and Gelinsky, 2015; Zhang *et al.*, 2014). In this view, striving to generate 3-D bodies with unique features, new technological approaches are needed, moving away from conventional protocols based on ceramic powder synthesis-processing-forming-sintering, towards chemical processes governed by concomitant nucleation/growth/assembling phenomena directly occurring in the 3-D state and giving bio-functional phases already consolidated in 3-D bodies with adequate porous structure. Nature can be a source of inspiration for the development of hierarchically structured biomaterials following a top-down approach (Limonov and Richard, 2016; Rezwani *et al.*, 2006). Indeed, the nano-sized building blocks forming the natural biological tissue is one of the bases of their self-organization ability and needs to be replaced by synthetic materials with controlled composition, structure and organization on multiple length scales (Suryanarayana, 1999). Following this approach, natural wood have been selected as starting point: it is, indeed, a cellular structure made of fiber bundles interconnecting channel-like porous areas with hollow tubes, and it can be considered as the elective template in starting the preparation of a new bone scaffold characterized by a biomimetic hierarchical composition and structure, exhibiting also a remarkable combination of high strength, stiffness and toughness at low density (Tampieri *et al.*, 2009). In Fig. 6 is illustrated a recent approach in which, a wooden structure, mimicking the osteon structure of the compact bone, was transformed into large bioactive, mechanically competent bone scaffolds by a multi-step process consisting in heterogeneous reactions established between reactive gases in the supercritical state and the solid 3-D templates.

Cylindrical wood pieces (*Calamus manna*) were preliminarily pyrolyzed at 1000°C to achieve a porous carbon body. The obtained body was then transformed into calcium carbide by heterogeneous reaction with gaseous calcium and then, oxidized at calcium oxide. Then, the subsequent transformation into highly reactive CaCO_3 precursor was carried out under wet conditions, by reaction with supercritical, hydrated CO_2 at high gas pressure. The heterogeneous reactions between CO_2 gas in supercritical state and solid biomorphic CaO templates, allowed the kinetic control of the temperature- and time-dependent grain growth and made possible to maintain the primitive composition and nanostructure at the basis of desired functional performances (Beruto and Botter, 2000). The final conversion into biomimetic, multi-doped hydroxyapatite, was obtained by hydrothermal reaction at conditions permitting the conversion of the template into a 3D body made of nano-twinned lamellar hydroxyapatite with hierarchical multi-scale porous architecture inherited by the natural wood template. Such a process could be carried out by thorough kinetic control of the temperature- and time-dependent grain growth making possible to retain high reactivity in the intermediate precursors and allow the achievement of the desired phase as a 3-D scaffold with bioactive composition and damage-tolerant mechanical performance. In fact, it was found that the uncontrolled grain growth of CaCO_3 and the lowering of specific surface area led to a poorly reactive phase affecting the subsequent transformation of CaCO_3 into hydroxyapatite by the hydrothermal method.

A bioreactor study was made, as a clinically-reflective approach for initial in vitro screening. The results highlighted a significant effect of the biomorphic scaffold on the up-regulation of various genes involved in both early (BMP2, Runx2 and ALP) and late (OPN and Col15a1) stages of osteogenic commitment (Orlando *et al.*, 2013; Thurner *et al.*, 2010), when compared to a porous sintered apatite scaffold (Fig. 7).

In vivo tests confirmed the excellent osteoinductive ability of the biomorphic scaffold, showing well developed bone tissue in ectopic site 12 weeks after subcutaneous implantation in rabbits. The histological analyses show both osteogenesis, osteoclastogenesis and angiogenesis, with abundant woven bone structures and a neovascular network penetrating through the scaffold and, further, the presence of active osteoclasts into surface depressions at the new woven bone surface report on bone resorption, typical of normal bone remodeling (see Fig. 8).

Fig. 7 Relative quantification ($2^{-\Delta\Delta\text{Ct}}$) of gene expression after 14 days of dynamic cell culture. Fold-change expression of the target genes induced by B-HA samples in respect to S-HA samples, used as a calibrator, are shown in the graph. Two-way ANOVA analysis indicated statistical difference between the samples with $p \leq 0.0001$. Reproduced from Tampieri, A., Ruffini, A., Ballardini, *et al.*, 2019. Fig. 9 X-ray image of a biomorphic bone scaffold implanted in critical metatarsus defect in sheep.

Particularly, the multi-scale porous structure, closely reproducing the lymphatic system of natural woods, is a key feature to promote vascular development throughout the whole scaffold. Recent results highlighted that the cross talk between endothelial and mesenchymal stem cells can be stimulated by such a biomimetic structure, very relevant to support bone and vascular regeneration, particularly in long bone segments, where the lack of vascularization is a major concern. Besides, the scaffold was implanted in critical size, load-bearing bone defect in a sheep model, showing excellent mechanical properties and adaptability to long bone defects, as shown in the radiography in **Fig. 9**, and ability to induce complete bone remodeling.

The obtained results highlighted how heterogeneous chemical processes carried out under unusual experimental conditions permitting the strict control of reaction kinetics in the 3D state permit to transform natural structures into inorganic devices inheriting their complex 3-D geometries, optimized in millions of years of evolution for optimal functional and mechanical performance.

Furthermore, such a hierarchic pore structure was found to be the source of outstanding, damage-tolerant mechanical performance, unusual for pure ceramics. In particular, the extremely intricate organization and interconnection of the channel-like pores of the biomorphic apatite effectively hinders crack propagation so that the fracture dynamics of the biomorphic ceramic under compression results very close to that of the starting wooden template and, also, to the one of natural bone tissue. Besides, the channel porosity of the wooden template closely resembling the osteon structure of compact bone, yields anisotropic mechanical properties that also results in flexure strength higher than compression strength, which is quite uncommon for ceramics, but very interesting in the view of application as scaffold for long bone segments where not only compressive forces but also the flexural ones, can be relevant.

These outstanding results report on the association of unique physicochemical and mechanical properties, obtained only thanks to a fabrication process revolutionizing the previous ceramic approaches. This is encouraging for the future development of functional 3-D ceramics so far prevented by inherent technological limitations. The excellent cell-instructive ability of the biomorphic scaffold, as induced by a bioactive scaffold recapitulating chemistry, nanostructure, structure and mechanics of the natural bone, demonstrates the validity of the “biomimetic concept” and – most importantly – suggests that biomimetic scaffolds alone can favor metabolic processes yielding tissue regeneration without the aid of additional growth factors, bioactive molecules and cells. This has a great impact on translational processes where it will be possible to avoid complex regulatory and storage issues, thus drastically shortening the time required for translation “from the bench to patient” and reducing the healthcare costs.

Magnetic Scaffold to Boost Tissue Regeneration

Previous studies show that the decrease in the regenerative potential in the elders or in presence of degenerative diseases is related to functional changes in adult stem cells with ageing. Such modifications include ability to proliferate, to form single cell-derived colonies and also differentiation capacity. Indeed, osteogenic and chondrogenic differentiation of stem cells undergo significant impairment with ageing, that negatively impact on new tissue formation (Hou *et al.*, 2013). Since biomimetic scaffolds are intended to effectively drive bone tissue regeneration, also providing progressive replacing of the scaffold itself with new healthy tissue (bio-resorption process), the patients’ metabolism plays an important role in the regulation of the kinetics and extent of new tissue formation. For this reason, metabolic diseases, as well as the degenerative conditions induced by aging, are a concern because the healing of damaged or missing tissues is significantly reduced. Since the occurrence of degenerative diseases is expected

Fig. 10 Scheme of the synthesis and macroscopic view of iron-doped hydroxyapatite.

to steadily rise in the next decades, the need to treat an ever increasing number of patients with impaired endogenous potential pushes the Material Science research towards new therapeutic approaches to boost cell functions and tissue regeneration. The use of drug delivery systems to release bioactive molecules directly in situ is a hot research topic in materials science. Particularly, the possibility to activate and control the release by remote signaling to obtain on demand delivery in temporally and spatially defined fashion, is a target extremely relevant, to improve the effectiveness and personalization of the therapy.

In this respect, recent studies report that the use of weak magnetic fields can be beneficial as remote signaling to permit non-invasive control of biomedical devices in vivo. The use of magnetic materials in nanomedicine is raising a steadily growing interest, due to the numerous possible applications including cancer therapy by hyperthermia, magnetic resonance imaging and other theranostic approaches based on the guiding of magnetic NPs to specific targeted areas in vivo and their use as nano-probes. This represents a very interesting and promising tool for new personalized therapies (Meng *et al.*, 2013, 2010; Mertens *et al.*, 2014; Panseri *et al.*, 2013; Shan *et al.*, 2013; Lewinski *et al.*, 2008). However, the currently used superparamagnetic iron oxides NPs (SPION, i.e.: mainly magnetite and maghemite) exhibit long-term toxicity by progressive accumulation in soft tissues and organs such as liver and kidney (Singh *et al.*, 2010; Tampieri *et al.*, 2012). Recent studies developed a new biocompatible and bioresorbable superparamagnetic phase by doping the hydroxyapatite lattice with $\text{Fe}^{2+}/\text{Fe}^{3+}$ ions in the two independent crystal sites of calcium (FeHA) (Tampieri *et al.*, 2011) (see Fig. 10).

This approach was attempted with the purpose of creating Fe-rich sublattices in the HA crystal, whose interaction could induce superparamagnetic behavior as Fig. 10 illustrates. Previous studies based on computer simulations had indicated that both divalent and trivalent Fe ions could be introduced in the HA lattice at different Ca crystal sites (Jiang *et al.*, 2002). Hence, the synthesis of superparamagnetic Fe-doped HA was carried out in conditions of pH and temperature preventing the oxidation of Fe^{2+} and the crystallization of undesired magnetite phase. The analysis of the crystal changes in respect to Fe doping confirms the substitution of Ca^{2+} in the lattice. Further studies (Iannotti *et al.*, 2017) reported on the segregation of Fe^{3+} on the surface of the HA crystals where they induce the heterogeneous nucleation of maghemite nanocrystals in very few amount (i.e., $\sim 2-3$ wt%). The distribution of the Fe ions in the apatitic and non-apatitic regions of HA structure confer complex magnetic properties enabling unique bio-functionalities (Tampieri *et al.*, 2012).

Thanks to the close similarity with the mineral bone composition, FeHA exhibits very good biocompatibility and enhanced cell proliferation and differentiation, if compared to the un-doped HA. Very interestingly, this effect was significantly increased when a static magnetic field was applied (Panseri *et al.*, 2012; Clavijo-Jordan *et al.*, 2012; Patricio *et al.*, 2019).

As reported in Fig. 11, FeHA is an excellent candidate in nanomedicine and regenerative medicine because its features can be customized changing size, morphology and combining with different polymers. Three different applications have been investigated: (1) the development of magnetic nanobeads suitable for the transportation of bioactive molecules; (2) the possibility to internalize it in cells; (3) the biomineralization of FeHA into collagen fibers to create magnetic hybrid scaffold for tissue engineering.

- (1) The possibility offered by the biomineralization process to generate nano-composites with superparamagnetic properties opens to the possible development of hybrid carriers with enhanced functionality, by using single or blended bio-polymeric matrices (Patricio *et al.*, 2017; Campodoni *et al.*, 2016). In particular, alginate is attractive due to its ability to bind to different monovalent ions, generally to create water soluble products, or bivalent ions such as Ca^{2+} , to create insoluble hydrogel, film, beads, nanoparticles thanks to the linking with Mannuronic and Guluronic units, that yields a typical “egg-box” structure (De and Robinson, 2003; Chen *et al.*, 2006; Zhao *et al.*, 2012; Eiselt *et al.*, 2000).

In particular, Campodoni *et al.* followed a biomineralization approach to synthesize a superparamagnetic hybrid nano beads consisting of Fe-doped apatite nanocrystals nucleated onto alginate polymeric matrices (Alg-FeHA). Starting from Alg-FeHA, superparamagnetic hybrid nanobeads (MHNs) were formed by a subsequent emulsification by oil-in-water technique. Importantly, the amount of alginate results very low, thus not affecting the magnetization values of MHNs in respect to the free magnetic nanoparticle. MHNs can be activated and deactivated by varying the intensity and the frequency of external magnetic fields; moreover, it is possible to guide them in specific therapeutic site where they can eventually release on

Fig. 11 An overview about the different applications in which magnetic materials can be exploited.

demand the relevant payload. Indeed, the design and magnetic ability of these particles enables enhanced drug protection against early degradation, as well as to avoid undesired or passive release inside of the target cells (Campodoni *et al.*, 2016). Hybrid magnetic devices can be also obtained in the form of hollow micro-nano spheres (Gloria *et al.*, 2013; Iafisco *et al.*, 2013; Nappini *et al.*, 2011) enabling multiple functionalization, by taking advantage of the active surface sites of the polymer and the mineral phase. Interestingly, their bioactivity can be tailored by the amount of FeHA phase so that they displayed good biocompatibility with bone marrow mesenchymal stem cells, and their proliferation was enhanced by higher amounts of FeHA phase. These magnetic materials have potential uses as building blocks for the preparation of scaffolds able to release different therapeutics on demand by remote activation through alternate magnetic fields. Such a stimulus can be dosed to obtain mild effect (magneto-shaking), permitting to deliver the payload with controllable kinetics or to trigger hyperthermia effect by which spheres can be disrupted thus releasing the bioactive agent (Liu *et al.*, 2016) in a more intense fashion, to provide a boosting effect. These approaches are still at their infancy but the growing interest in obtaining more effective and stimuli-responsive devices for regenerative medicine will definitely push deeper research in the field (Plouffe *et al.*, 2015).

- (2) As an alternative to drug delivery, magnetic fields can be used for cell manipulation and guiding to specific target sites. Magnetic-based cell separation technology is a recent approach, aimed to improve the selection, sorting and handling of stem cells, which can be the basis of personalized cell and gene therapies (Tampieri *et al.*, 2003). Such approach can be used to improve the effectiveness of implanted scaffolds, which is particularly relevant for tissue regeneration in the elderly (Sprio *et al.*, 2014). In fact, since ageing implies a reduced number and activity of stem cells, the cell population of implanted scaffolds can be impaired and ineffective, thus resulting in low extent of new tissue formation. The use of magnetic NPs open new scenarios in this respect; in fact, a key limiting factor in the regeneration of extended bone defects is the inability of cells to self-propagate in the inner part of the scaffold and to establish new bone and vascular tissue (Ganguly and Puri, 2010). Recent studies show that it is possible to locally guide the migration of magnetic NPs and NP-labeled cells through the use of an externally applied magnetic field gradient (Amer *et al.*, 2017). In this respect, FeHA NPs showed to be easily incorporated into cells by endocytosis, thus obtaining “magnetic cells” without negatively affecting the cell behavior (e.g., proliferation, morphology, differentiation). Besides the beneficial effect given by enhanced scaffold population, this approach can greatly widen the perspective of application of cell therapies, since magnetic guiding with biocompatible NPs can help to improve the cell retention and viability post-injection that are among the most critical obstacles facing clinical translation (Amer *et al.*, 2017).
- (3) The achievement of biocompatible nano-biomaterials with magnetic properties opens new perspectives not only in nano-medicine, as described above, but also in Regenerative Medicine with the development of new biomedical devices with ability of remote activation and switching of high socio-economic impact. Indeed, the development of scaffolds enhancing

bone regeneration by remote magnetic activation is an emerging concept in Regenerative Medicine (Assiotis *et al.*, 2012), since it has been demonstrated that weak magnetic or pulsed electromagnetic fields are effective in promoting bone fracture healing, spinal fusion and bone ingrowth in animal models (Chalidis *et al.*, 2011; Glazer *et al.*, 1997; Grace *et al.*, 1998; Yan *et al.*, 1998; Panseri *et al.*, 2012). Moreover, several previous works have demonstrated that magnetic scaffolds have a positive effect on osteoinductivity with and without application of external magnetic forces. However, the incorporation of magnetic phases into ceramic bone scaffolds is made difficult by the need of consolidating green ceramic bodies by a high temperature treatment that often provokes oxidation of superparamagnetic iron oxides and losing of magnetic properties (Tampieri *et al.*, 2014). In this respect a bio-inspired fabrication process such as biomineralization (see previous paragraph) permitted to retain the fine physicochemical features determining enhanced bioactivity in FeHA and to develop 3-D magnetic hybrid scaffolds with mineralization extent that could be tailored from cartilage to bone-like level (Banobre-Lopez *et al.*, 2011), thus permitting its application as a magnetic scaffold, very promising to boost regeneration of critical size bone and osteochondral defects.

Future Perspectives

Under the pressure of still unmet industrial and societal needs requiring smart materials and devices, material science is today experiencing great impulses, with the purpose to discover new ways for fabrication of smart 3-D bioceramics. A prominent target is the achievement of consolidated bodies by low energy processes, aiming to retain nanostructure and biofunctional ability typical of nanocrystalline, metastable phase compositions. In future decades, material scientists will be called to explore completely new pathways based on chemical reactions carried out in non-equilibrium conditions rather than under stable thermodynamic regimes.

A main general concept emerging today in Material Science is to draw inspiration from Nature to obtain functional 3-D ceramics: to this purpose, the hydrophobic features of lotus flower, the adhesive ability of geckos, the inimitable mechanical properties of web spider and the dynamically active mechanical response of organisms such as the Echinoderms are just some examples that scientists will try to mimic. Particularly, the achievement of materials able of complex and adaptive mechanical performance is among the hardest challenges for biomaterial scientists. In fact, in Regenerative Medicine it is increasingly evident that, besides chemical recognition by cells, appropriate dynamic mechanical stimulation is key to activate and support the formation and maturation of new load-bearing tissues. The development of such new devices could open to regeneration of complex anatomical regions subjected to loading. Particularly relevant in this respect are the osteochondral tissues of the joints which, in modern life, are frequently subjected to degenerative pathologies and thus seriously jeopardize the mobility and quality of life of an ever increasing number of aged patients. In this respect, new mechanically active scaffolds could be the key to stimulate the simultaneous regeneration of bone and the articular cartilage in large degenerated regions, targeting the achievement of a completely resorbable “Bioprosthesis” completely replacing the invasive metal-based prosthesis.

Another growing field in biomaterial science is the development of functional nanoparticles for nanomedicine. Today, the use of toxic metal or metal oxide NPs is pushing scientists to complex approaches for creating bio-friendly interfaces with cells. On the other hand, NPs are called to function as active devices for theranostics, that is bio-sensors and drug deliverers. Biomimetic and bioactive ceramic nanoparticles are emerging as relevant candidates to replace metal-based devices, thanks to their chemical affinity with human hard tissues, ability to directly induce a positive cell response by chemical recognition, and to their reabsorbability, thus opening to safer applications and ability to provide clearer response for disease detection. This has great relevance for more targeted and personalized applications in nanomedicine and can respond to urgent needs related to the ageing of the population, envisaged to reach the maximum peak within the incoming two decades.

Introduction

Ceramics are characterized by strong atomic bonds and in consequence exhibit a high stiffness expressed by a high value of Young's modulus and a brittle behavior which means without plastic deformation. Ceramics present a low tensile strength and a high compressive strength. The mechanical behavior is very sensitive to the presence of surface or volume flaws like grooves and pores. Ceramics have also a high hardness and so exhibit a good wear resistance. Owing to all these mechanical properties and their bio-inertia, aluminum, and zirconium oxides and composites are commonly used as structural parts like hip joint, knee prosthesis, dental implant. Contrarily, other ceramics such as calcium phosphate, carbonate or silicate, whose chemical composition is close to that of natural bone, are rather used for their osteoconductive properties as bone repairing material. In this paper, the mechanical behavior of these ceramics is largely described.

Mechanical Behavior

Elastic Behavior

The elastic modulus or Young's modulus depends on the bond stiffness and the interatomic distance. Ceramics exhibit two bond types: ionic and covalent which have a high bond stiffness. So, the elastic modulus of ceramics is rather high. Diamond has a Young's modulus equal to 1000 GPa, alumina 390 GPa, zirconia 205 GPa, hydroxyapatite 110 GPa, and glass 70 GPa.

The elastic modulus decreases with increasing the volume fraction of porosity P following the empirical equation:

$$E = E_0(1 - 1.9P + 0.9P^2) \quad (1)$$

where E_0 is the elastic modulus of the dense material.

So, the elastic modulus of alumina decreases from 390 GPa to 100 GPa for a volume fraction porosity equal to 40%.

The elastic modulus decreases equally when microcracks appear.

Hardness

Due to the strong interatomic bonds, ceramics exhibit high hardness. Diamond is the hardest material (Vickers hardness $HV = 9000$), alumina $HV = 2300$, zirconia $HV = 1400$. The hardness as the elastic modulus depends on the porosity.

Mechanical Strength

The mechanical strength of ceramics exhibits large variations and depends on the grain size, porosity, reinforcement mechanisms. The ceramics are brittle and thus, the mechanical strength depends essentially on the flaw (or crack) size. This size is related to the microstructure obtained after fabrication (pores, flaws, cracks). The strength variation is related to the size distribution of the flaws. This variation can be described by using a statistical function and the empirical Weibull approach is very often used. This approach based on the weakest link gives the failure probability as a function of stress σ and volume V of ceramic

$$P(V) = \exp\left[-V\left(\frac{\sigma - \sigma_u}{\sigma}\right)^m\right] \quad (2)$$

σ_u = stress below which failure has zero probability, σ_0 = normalizing parameter and m = Weibull modulus.

The Weibull modulus reflects the width of the strength distribution. The higher m is, the lower is the strength variation. Values of m between 5 and 20 are often obtained. An example of such a distribution for alumina is given by the Fig. 1 (the Weibull modulus m is about 20). Practically, the strength variability must be reduced and highest m values must be obtained.

As for elastic modulus, the mechanical strength decreases with increasing the volume fraction of porosity. For alumina, the bending strength can vary from 300 MPa down to 50 MPa for an alumina with 30% porosity. The decrease can be described by the following empirical equation:

$$\sigma = \sigma_0 \exp(-\alpha P) \quad (3)$$

with σ = mechanical strength for dense ceramic.

α = constant (in the range 4–7).

So, porous ceramics exhibit low mechanical strength.

This effect of porosity is very significant for the use of calcium phosphate bone substitutes and has a detrimental influence on the mechanical strength which influences the device handiness for surgeons. Fig. 2 shows the variation of compressive strength of two bone

Fig. 1 (a) Failure probability of alumina as a function of 4-points bending stress; (b) Weibull analysis (Eq. (2): the slope is equal to m).

Fig. 2 Compressive strength versus pore volume fraction for bone substitutes processed with 300–600 μm and 600–1250 μm porogen particles. From Bignon, A., Chouteau, J., Chevalier, J., *et al.*, 2003. Effect of micro- and macroporosity of bone substitutes on their mechanical properties and cellular response. *Journal of Materials Science: Materials in Medicine* 14, 1089–1097.

substitutes constituted of hydroxyapatite (HAP) and β -tricalcium phosphate (β -TCP) with a weight ratio of 70:30 processed with two sizes of porogen particles (300–600 μm and 600–1250 μm) and sintered at 1125°C during 15 h (Bignon *et al.*, 2003). Two types of pores must be considered: micro- and macroporosities, the last ones being of major importance, ceramics being sensitive to the largest defects. The results obtained for the two porogen particle sizes are well described by Eq. (3) but with different α parameters ($\alpha = 2$ and 4 for 300–600 μm and 600–1250 μm sizes, respectively). The largest defects being macropores, the strength of 600–1250 μm ceramics is lower. The strength depends also on the grain size and the presence of micropores: the larger the grain size, the lower the strength.

Toughness

Based on fracture mechanics, the fracture toughness of a brittle ceramic corresponding to the crack growth resistance can be evaluated by the critical stress intensity factor K_{IC} given by the Griffith criterion

$$K_{IC} = \sigma_f Y a_c^{1/2} \quad (4)$$

where σ_f = fracture strength, a_c = critical flaw size and Y = non dimensional geometrical factor.

The fracture toughness of ceramics is in the range 1–10 MPa m^{1/2} and the presence of flaws or cracks with a size of the order of some μm is responsible for the ceramic failure.

Very often, the toughness increases with crack growth and the fracture behavior is described by a crack growth resistance curve (R-curve), representing the stress intensity factor K_R with the crack extension Δa . Generally, K_R increases with a decreasing slope from an initial value (intrinsic fracture toughness) up to a plateau. The crack becomes unstable when the strength σ_f is reached with $K=K_R$ and $dK/da=dK_R/da$. So, the strength improvement of ceramics is related to the slope of the R-curve and the early part of this R-curve.

In order to improve the mechanical properties, particularly toughness, several mechanisms of reinforcement can be used (Fantozzi and Chevalier, 2020): phase transformation, microcracking, crack deflection, crack bridging, and fiber or whisker reinforcement.

Microstructural Toughening

Concerning bioceramics, the most important used reinforcement mechanisms are grain (crack) bridging and transformation toughening. These toughening mechanisms act as crack-shielding mechanisms due to the closure stresses acting in the wake of the propagating crack. The resulting R-curve as a function of crack propagation Δa can be written as follows:

$$K_R(\Delta a) = K_0 + K_{sh}(\Delta a) \quad (5)$$

where K_0 = intrinsic fracture toughness, K_{sh} = toughening increment.

The toughening increment is higher for phase transformation (up to 15 MPa m^{1/2}) than for grain bridging (2–5 MPa m^{1/2}).

Grain (Crack) Bridging

This reinforcement occurs when a crack meets a grain (or a particle) without breaking it. An example of grain bridging in alumina is shown by Fig. 3. The crack-tip shielding is due to elastic and interfacial frictional stresses which reduce the crack opening. This shielding results in a reduction of the effective stress intensity factor and thus enhances the material toughness. The grain bridging magnitude depends on the grain size and aspect ratio. Elongated grains enhance the frictional bridging and pull-out and result in a more significant R-curve behavior. Fig. 4 shows such an effect for coarse grained alumina (El Attaoui *et al.*, 2005) which exhibits a higher fracture resistance when the grain size increases.

The increase of fracture toughness must lead to an increase of fracture strength following Eq. (4) if the critical flaw size is constant. But generally, for monolithic ceramics the flaw size varies as the grain size: $a_c = \alpha d_{\max}$, $d_{\max}$ = maximum grain size and α = constant (between 5 and 10). So, the increase of flaw size is more important than the increase of fracture toughness and thus the fracture strength decreases very often when the grain size increases. As a result, fine grain alumina ceramics exhibit better mechanical strength than coarse grain ones.

Fig. 3 SEM micrograph of grain bridging in alumina. From Fantozzi, G., Saadaoui, M., 2014. Toughness, fatigue and thermal shock of ceramics: Microstructural effects. In: Sarin, V.K., Llanes, L., Mari, D. (Eds.), *Comprehensive Hard Materials*. Elsevier, pp. 299–319.

Fig. 4 K_R curves for alumina with different grain sizes. From Fantozzi, G., Saadaoui, M., 2014. Toughness, fatigue and thermal shock of ceramics: Microstructural effects. In: Sarin, V.K., Llanes, L., Mari, D. (Eds.), *Comprehensive Hard Materials*. Elsevier, pp. 299–319.

Transformation Toughening

Increase in mechanical strength and fracture toughness can be obtained by stress-induced phase transformation (Green *et al.*, 1989). The most significant results are observed for a large variety of zirconia-toughened ceramics (ZTC) which can be classified into different types following their microstructure (Hannink *et al.*, 2000):

- (1) Toughened ceramics with tetragonal zirconia particles in a ceramic matrix: the most known is zirconia toughened alumina (ZTA).
- (2) Partially stabilized zirconia (PSZ) constituted of tetragonal precipitates dispersed in a cubic zirconia matrix, obtained by doping with some stabilizers (as magnesia).
- (3) Tetragonal zirconia polycrystals (TZP) with the tetragonal phase retained at room temperature by addition of a stabilizer. The most commons are Y-TZP and Ce-TZP ceramics with yttria and ceria stabilizers respectively.

Transformation toughening is linked to the stress-induced martensitic tetragonal (t) to monoclinic (m) transformation of zirconia grains or particles which takes place in the wake of the crack. This phase transformation occurs with a volume increase (about 5%) and a shear strain which lead to the appearance of compressive stresses shielding the crack tip and hindering the crack opening. Therefore, the crack propagation needs an increase of the applied stress intensity factor in order to overcome the shielding contribution K_{sh} (Eq. (5)). The crack growth resistance increases and reaches a plateau corresponding to a steady-state transformation zone.

The increase of the transformation toughening is related to the stability of the tetragonal phase which depends on microstructural characteristics such as particle or grain size. There is a critical stress for transformation σ_c , the higher the grain size is, the lower is σ_c and therefore the higher are the volume fraction of transformed particles and the toughness increase. But, if the grain size becomes higher than a critical size, spontaneous transformation occurs during cooling and most grains or particles are transformed before crack propagation and the toughening disappears.

Phase transformation in ZTC is often accompanied by other mechanisms such as microcracking or grain bridging which can contribute also to the toughening.

Mechanical Properties of ZTC

Some mechanical properties of different ZTC are given in the Table 1.

Crack growth resistance curves of some ZTC are shown in Fig. 5. It can be noticed that higher R-curve effect is observed for the Mg-PSZ or Ce-TZP ceramics.

Some interesting combinations of mechanical strength and fracture toughness have been obtained with Ce-TZP ceramics or composites (Touaiher *et al.*, 2018; El Attaoui *et al.*, 2007). As shown by Fig. 6, a strong R-curve behavior is observed for a ceria content of the order of 10–11 mol%, which is due to an autocatalytic phase transformation. If the ceria content is too high, the level of transformability is lower because the tetragonal phase is more stable and then the toughness is lower. Fig. 7 shows the autocatalytic transformation zone for the 10Ce-TZP ceramic observed during a crack propagation observed by double torsion test.

The variation of the mechanical strength versus the fracture toughness of Y-TZP, Ce-TZP, or Mg-PSZ ceramics is shown in Fig. 8. Y-TZP ceramics largely used for biomedical applications exhibit high strength (~ 1 GPa) with a moderate toughness. Besides, Ce-TZP or Mg-PSZ present high toughness with a moderate strength (~ 500 MPa). The fracture of high strength ceramics is governed by the intrinsic flaws whereas the high toughness ceramics exhibit a strength limited by the t-m transformation, the

Table 1 Mechanical properties of ZTC

Ceramic	Mg-PSZ	Y-TZP	ZTA	Ce-TZP
Density (g cm^{-3})	5.75	6.05	4–5	6.1–6.2
σ_f (MPa)	500–700	1000–1500	600–1000	400–800
K_{IC} ($\text{MPa m}^{1/2}$)	6–9	8–12	6–10	6–15
E (GPa)	185–205	200	250–350	190–200
Hardness HV (GPa)	11–12	12	16–18	7–13

**Fig. 5** K_R curves for different zirconia toughened ceramics. From Hannink, R.H.J., Kelly, P.M., Muddle, B.C., 2000. Transformation toughening in zirconia-containing ceramics. *Journal of the American Ceramic Society* 83, 461–487.**Fig. 6** K_R curves of Ce-TZP ceramics. From El Attaoui, H., Saadaoui, M., Chevalier, J., Fantozzi, G., 2007. Static and cyclic crack propagation in Ce-TZP ceramics with different amounts of transformation toughening. *Journal of the European Ceramic Society* 27, 483–486.

transformation zone size becoming comparable or larger than the intrinsic flaws and the strength is insensitive to the initial flaw size.

So, new Ce-TZP based composites have been developed recently with a microstructure refinement in order to improve the mechanical strength: Ce-TZP/alumina, Ce-TZP/ MgAl_2O_4 nanocomposites and platelets reinforced Ce-TZP composites with alumina and strontium or lanthanum aluminate (Touaiher *et al.*, 2018).

The Ce-TZP with 11.5 mol% CeO_2 , 8 vol% alumina, 8 vol% strontium aluminate exhibits a fracture toughness of $10.6 \text{ MPa m}^{1/2}$ with a bending strength higher than 700 MPa. Furthermore, this material does not present low temperature degradation.

Concerning ZTA ceramics, the reinforcement depends on the volume fraction of transforming particles, the particle size and the yttria content. Fracture toughness presents a maximum with increased zirconia content. This maximum occurs for higher zirconia content when the particle size decreases and is shifted towards high volume fraction as the yttria content increases. ZTA exhibit values of fracture toughness up to $10 \text{ MPa m}^{1/2}$ and mechanical strength up to 1 GPa.

Subcritical Crack Growth

For many ceramics, the presence of a reactive environment provokes cracks to grow at a stress intensity factor lower than the fracture toughness K_c and can lead to delayed fracture. The basic mechanism responsible for this slow crack growth is the stress-enhanced chemical interaction between environmental species (as water) and the crack tip bonds, the crack growth rate being determined by the reaction kinetics. This slow crack growth is linked to the stress intensity factor K_I by a power law between the crack growth rate and K_I : Eq. (6) K_I^n

$$V = da/dt = A K_I^n \quad (6)$$

With A and n = constants depending on the material, cracking region and environment-ceramic interaction.

The lifetime prediction for ceramic components can be deduced from this slow crack growth rate by determining the time necessary to reach the critical flaw size given by Eq. (4) corresponding to the applied stress σ .

Typical V - K_I curves are shown in Fig. 9 for a 3Y-TZP zirconia doped with 3 mol% of Y_2O_3 . Under vacuum, water and air conditions, the presence of a threshold below which there is no propagation can be noticed. The V - K_I curve in air comprises three stages. For the stage I (low crack growth rates), the rate-limiting mechanism is the reaction between the ceramic and corrosive molecules (water) at the crack tip provoking the fracture of ceramic bonds. The stage II is controlled by the transport of molecules from the crack mouth up to the crack tip. The stage III takes place for higher crack rates and corresponds to the fracture of ceramics bonds without reaction with environment. In water, only the stage I occurs and under vacuum stage III appears for a stress intensity factor near K_{IC} .

The sensitivity of ceramic to stress assisted corrosion and slow crack growth is related to the aptitude of reaction with water and it is strongly linked to ionic fraction of the bond (higher the ionic fraction, higher the sensitivity).

For polycrystalline ceramics, the slow crack growth behavior is linked strongly to the microstructure, especially for reinforced ceramics.

Fig. 9 Crack velocity V - K_I curves of a Y-TZP zirconia. From Chevalier, J., Fantozzi, G., 2005. Slow crack propagation in ceramics at the nano- and micro-scale: Effect of microstructure. In: Bradt, R.C., Munz, D., Sakai, M., White, K.W. (Eds.), *Fracture Mechanics of Ceramics 14*. New York: Springer, pp. 173–190.

Fig. 10 Crack velocity V - K_I curves for three alumina with different grain sizes. From Ebrahimi, M.E., Chevalier, J., Fantozzi, G., 2000. Slow crack growth behavior of alumina ceramics. *Journal of Materials Research* 15, 142–147.

The driving force for slow crack growth corresponds to the effective crack tip stress intensity factor K_{tip} taking into account the crack shielding K_{sh} due to the reinforcement:

$$K_{tip} = K_I - K_{sh} \quad (7)$$

For non-transforming ceramics, the grain size has a significant effect on slow crack growth due to the grain bridging reinforcement. By increasing the grain size, the shielding effect of bridging increases. **Fig. 10** shows the V - K_I curves obtained in air for three polycrystalline alumina with different grain sizes.

The slow crack growth controlled by stress corrosion is very sensitive to the stress intensity factor in the stage I and when the grain size increases, the V - K_I curve is shifted toward higher stress intensity factor with a higher slope of the power law. Moreover, the threshold is higher for the coarse grained alumina than for the fine grained alumina.

It can be noticed that the shielding effect of grain bridging is observed only for the intergranular mode of fracture and for largest grain size, a shift of the V - K_I curve towards low stress intensity factor occurs corresponding to the appearance of a transgranular fracture mode without grain bridging effect (Ebrahimi *et al.*, 2000).

For zirconia toughened ceramics, the effect of phase transformation toughening on the slow crack growth must be taken into account. The transformation zone size increases with the applied stress and thus the shielding stress intensity factor is proportional to the applied stress intensity factor:

$$K_{sh} = C_{sh} K_I \quad (8)$$

C_{sh} is a parameter which increases with the material transformability.

The intrinsic mechanism of slow crack growth can be attributed to a stress corrosion mechanism at the crack tip and is given by

$$V = A_0 K_{tip}^n \quad (9)$$

A_0 = intrinsic parameter.

Fig. 11 Crack velocity V - K_I curves of Ce-TZP composites. From Touaiher, I., Saadaoui, M., Chevalier, J., Preiss, L., Reveron, H., 2018. Fracture behavior of Ce-TZP/alumina/aluminate composites with different amounts of transformation toughening. Influence of the testing methods. Journal of the European Ceramic Society 38, 1778–1789.

So, from Eqs. (7), (8) and (9), the V - K_I law when zirconia particles exhibit phase transformation becomes:

$$V = A_0(1 - C_{sh})^n K_I^n \quad (10)$$

The transformation toughening effect on slow crack growth shifts the V - K_I law towards the high stress intensity factors. C_{sh} depends on the stability of the tetragonal phase.

The slow crack growth curves of Ce-TZP zirconia composites are shown in Fig. 11 and compared with 3Y-TZP, Ce-TZP/alumina nanocomposite, and Ce-TZP/magnesium aluminate spinel (Touaiher *et al.*, 2018).

The Ce-TZP composites contain 8 vol% alumina and 8 vol% strontium hexa-aluminate with a CeO_2 stabilizer content of 11 and 11.5 mol%. One composite HT (sintered at 1500°C) corresponding to the lower ceria content (11 mol%) exhibits a large transformation zone, the LT composite (sintered at 1450°C) corresponds to the higher ceria content (11.5 mol%) and presents a lower transformability and the third one MT (11.5 mol%, sintered at 1500°C) exhibits a medium transformability.

For the MT and HT composites, the V - K_I curve is shifted toward very high toughness values, corresponding to a high value of C_{sh} (Eq. (8)): the higher the transformability, the higher the V - K_I shift and the threshold intensity factor K_{I0} . Transformation toughening requires zirconia particles with a size between the critical size for spontaneous transformation and the critical size for stress induced transformation.

Fig. 12 shows the microstructure of two ZTA composites (De Aza *et al.*, 2003): the first one A-10Z corresponds to a narrow distribution of nano-size zirconia particles (10 vol%) distributed in a micrometer alumina matrix.

The particle sizes between 100 and 600 nm correspond to the maximum amount of transformation toughening and the V - K_I curve is shifted toward higher K_I values, compared to alumina and Y-TZP (Fig. 13). The A-2.5Z nanocomposites obtained with 2.5 vol% zirconia nanoparticles exhibit a peculiar behavior: both fracture toughness and threshold are increased. The size of zirconia particles (< 100 nm) is below the critical size for the stress induced transformation and so, there is no transformation toughening. The reinforcement of this composite is due to a compressive residual stress field in the matrix which hinders the crack front opening.

Among ceramics for medical applications, hydroxyapatite is a good candidate in orthopedics owing to the composition similar to the mineral part of bones and teeth. Slow crack growth behavior of dense hydroxyapatite has been investigated by Benaqqa *et al.* (2005). Fig. 14 shows the V - K_I curve determined in air for a hydroxyapatite with a grain size of 2 μm . The slow crack growth occurs below the toughness (0.9 MPa $m^{1/2}$), presents a threshold around 0.6 MPa $m^{1/2}$ and exhibits the classical three stages I, II, and III consistent with the stress corrosion by water molecules observed in oxide ceramics. Stage I has a primordial importance since slow crack rates rule the lifetime in service.

Cyclic Fatigue

Ceramics are sensitive to cyclic fatigue, especially if they exhibit a significant crack growth resistance (R-curve). Cyclic loading enhances slow crack growth compared to static loading: crack growth rates can be several orders of magnitude higher than those obtained with a static loading. The crack growth rate is very sensitive to the maximum applied stress intensity factor K_{max} (high value of the exponent m) compared to the stress intensity factor range ΔK . It is given by the modified Paris law:

$$da/dt = A(\Delta K)^p K_{max}^m \quad (11)$$

Fig. 12 SEM micrographs showing the microstructure of the A-10Z (a) and A-2.5Z (b) composites. From De Aza, A.H., Chevalier, J., Fantozzi, G., Schehl, M., Torrecillas, R., 2003. Slow crack growth behavior of zirconia-toughened alumina ceramics processed by different methods. *Journal of the American Ceramic Society* 86, 115–120.

Fig. 13 Crack velocity V - K_I curves for alumina, 3Y-TZP zirconia and composites A-10Z and A-2.5Z. From De Aza, A.H., Chevalier, J., Fantozzi, G., Schehl, M., Torrecillas, R., 2003. Slow crack growth behavior of zirconia-toughened alumina ceramics processed by different methods. *Journal of the American Ceramic Society* 86, 115–120.

Moreover, the threshold below which no crack propagation occurs is much smaller for cyclic loading compared with static loading. The intrinsic response to static or cyclic loading is the same, but a degradation of the reinforcement takes place during cyclic loading. The cyclic loading behavior is linked to the microstructural aspects of the reinforcement.

For non-transforming ceramics, the toughening is due essentially to crack bridging. During cyclic loading, there is a degradation of the bridging zone and a decrease of the shielding capacity. Accumulation of frictional-wear damage at the grain/matrix interface and reduction of frictional sliding resistance of partially debonded grains diminish bridging stresses and thus enhance crack growth rates under cyclic loading (Ritchie *et al.*, 2000).

Fig. 15 shows an example of such degradation for a coarse grained alumina (20 μm) exhibiting a significant R-curve behavior shown in Fig. 4. The specimen is first monotonically loaded until fully bridged crack was formed (plateau of the R-curve). Then the specimen is submitted to cyclic mode during 10,000 cycles with a maximum load lower than the load reached at the end of the monotonic loading. The degradation can be quantified by the drop of K_R without crack growth. Then after an incubation period, cyclic fatigue crack growth is initiated with an increase of K_R due to new bridging zones. A new steady-state equilibrium is reached taking into account the balance between the shielding effect of bridging during fatigue crack propagation and the cyclic degradation. The plateau value after cyclic fatigue is lower, the bridging effect being less effective than during monotonic loading.

Steady state crack growth rates as a function of $K_{\max}$ during cyclic loading for two alumina (A4 and A20 with respective grain size of 4 and 20 μm) are shown in Fig. 16 (the static loading results are also shown for comparison).

For the fine grained alumina which has a small R-curve effect (Fig. 4), the cyclic fatigue effect is very limited whereas for the coarse grained alumina the crack growth rate becomes higher up to several orders of magnitude in the low crack growth rate

region. The difference between the static and the cyclic loading is due to the shielding degradation during cyclic fatigue. The threshold for the cyclic loading tends toward the fine grain one. The benefit of crack bridging disappears for low cyclic load.

The same effect of cyclic fatigue was observed for Ce-TZP ceramics by *El Attaoui et al.* (2007). Several fatigue mechanisms intervene: wedge effect due to debris, bridging degradation, modification of the shielding effect of the transformation zone.

Low Temperature Degradation

The zirconia-toughened ceramics are very interesting materials but some particular zirconia ceramics exhibit a low temperature degradation in the presence of moisture. They suffer a slow t-m transformation at the sample surface in the presence of moisture which leads to microcracking strength loss. This phenomenon, presented as Achilles heel, was largely described by *Chevalier et al.* (2009).

The main features of the low temperature degradation are summarized as follows (*Chevalier et al.*, 1999; *Déville et al.*, 2003):

- (1) Transformation proceeds rapidly at 200–300°C and is time dependent.
- (2) Water or water vapor enhance the transformation.
- (3) The degradation is due to the t-m transformation accompanied by microcracking.
- (4) Transformation proceeds from the surface to the bulk of zirconia ceramics.
- (5) Higher stabilizing content or finer grain size increase the resistance to transformation.

The mechanisms responsible of the low temperature degradation are not firmly established. **Fig. 17** shows the low temperature ageing kinetics of different zirconia ceramics (*Chevalier et al.*, 2009) measured at 134°C in steam autoclave: 10Ce-TZP, Mg-PSZ, 3Y-TZP, A10Z0Y, and alumina-toughened zirconia (A80Z3Y) (The expected ageing times at 37°C are also indicated). The results show that ceria-doped zirconia have a better behavior than 3Y-TZP ceramics. It can be also noticed that alumina reinforced with a low content of zirconia is very resistant to low temperature degradation as the Mg-PSZ ceramics. For the ZTA ceramics, the transformation t-m occurs when the zirconia content exceeds the percolation threshold (~ 16 vol fraction) as shown by **Fig. 18**.

Introduction

Due to the specific type of chemical bonding, most ceramics are characterized by their biocompatibility, color stability, chemical durability, temperature resistance, wear resistance and ability to be formed into precise shapes, all of which make them very well suited for applications in dentistry. Indeed, during the past two decades, numerous types of ceramics and processing methods have been introduced, being one of the fastest growing areas in dental materials research and development. Dental ceramics comprise a wide variety of materials that reaches from silicate glasses, porcelain, glass-ceramics to dense polycrystalline sintered oxide ceramics and can be classified into different groups by their principal crystal phase and/or matrix phase, as shown in [Table 1](#). Note that a “composite” refers to a different material in the ceramic and dentistry field. A ceramic composite is a combination of two or more ceramic phases, such as ceramic particles or fibers embedded in a ceramic matrix; whereas a dental composite normally refers to a resin composite in which ceramic particles or fibers are embedded in a polymer matrix. Dental ceramics can be formed into inlays, onlays, veneers, crowns, and more complex fixed dental prostheses (FDPs). As a load-bearing part, the mechanical performance is one of the most important factors that a dental prosthesis has to fulfill in order to ensure its intended functions effectively and safely over extended periods of time. The mechanical properties comprise the elastic and/or plastic response of a material to deformation, crack growth or fracture under an applied force/pressure and the induced stresses, and can be expressed in units of stress and/or strain.

Ceramics are brittle in nature and the fracture of ceramics occurs with very limited plastic strain (commonly less than a few parts per thousand). They may fracture without warning when bended excessively or when quickly heated and cooled (i.e., under thermal shock conditions). The flexural or bending strength, that well resembles the stress condition of dental prosthesis as shown in [Fig. 1](#), is an important parameter to design the dental component. However, the strength of a ceramic is not an inherent material property since it varies under different conditions (processing route, specimen dimensions, specimen shapes, stress cycles, surface quality and the environment). In parallel, an adequate fracture toughness that describes the crack growth resistance of brittle materials is a true material-dependent property, and is an important requirement of any dental ceramic. This chapter introduces the basic principles of brittle fracture and fracture statistics. The mechanical resistance to fracture of different dental ceramics in correlation with their microstructure will be discussed. There are also questions on why dental restorations may fracture after a few years of service but not during the first month or year of clinical service? The mastication cyclic loading-unloading force in the oral cavity must somehow have reduced the mechanical resistance of the prosthetic material, due to the very slow but steady propagation of inherent flaws/cracks at loads that are smaller than the initial fracture load. This causes a loss of strength with time, and among the different mechanisms, fatigue and chemically-assisted slow crack growth are important phenomena for dental ceramics.

Fracture Mechanisms

While ceramics can exhibit a brittle or ductile behavior over different temperature ranges, brittle fracture mechanisms are inevitably the most important mechanism of failure of ceramics for dental applications close to room temperature conditions. In this case, flaws play a dominating role in their mechanical behavior. The early work of Griffith has shown that small cracks in glass can reduce the strength to only 1% of its theoretical strength ([Griffith and Taylor, 1921](#)). Flaws cannot be completely avoided and can be generated during processing or in service such as during sintering, handling of the green body, machining, contact damage, or corrosion. The flaws of different sizes can be located on the surface or dispersed in the bulk material, behaving like cracks. The propagation of such cracks in general leads to sudden and unexpected failure, i.e., catastrophic failure. Although mechanisms such as phase transformation, microcracking, crack deflection, crack bridging and pull-out can provide some resistance to crack propagation, they are less effective as compared to plastic deformation.

Cracks grow if the reduction of the stored elastic energy associated with the crack growth is larger than or equal to the additional surface energy needed to create the new free surfaces ([Griffith and Taylor, 1921](#)). Linear elastic fracture mechanisms based on stress (Irwin) or energy (Griffith) criteria can be used to describe the fracture of brittle ceramics assuming that the crack tip is infinitely sharp and embedded in an elastic continuum ([Lawn, 2010](#)). Under type I failure mode, which is the most important geometry for the failure of ceramics with an applied tensile stress that is perpendicular to the crack plane, a crack will propagate when the stress intensity factor (K_I) reaches or exceeds a critical value K_{IC} .

$$K_I = \sigma Y \sqrt{a} \geq K_{IC} \quad (1)$$

The stress intensity factor K_I describes the elastic stress field near the tip of a crack, σ is the applied stress and a the crack length. The factor Y is a dimensionless constant that depends on the geometry of the specimen and the crack, and on the gradients of the

stress field. Flaws in ceramic materials are usually very small in comparison to the specimen dimensions, and Y is independent of the crack length with $Y = \sqrt{\pi}$ for an internal flaw and $Y = \sqrt{\pi/2}$ for a surface flaw. K_{IC} , the critical value of K_I , i.e., the fracture toughness, at which the crack will propagate and lead to fracture is in principle an intrinsic material property. K_{IC} under plane stress conditions in mode I is defined as:

$$K_{IC} = (EG_c)^{1/2} \quad (2)$$

where E is the Young's modulus and G_c the energy absorbed per unit area of crack propagation, i.e., the strain energy release rate.

According the above mechanism, the fracture strength of ceramics can be written as

$$\sigma_f = \frac{K_{IC}}{Y\sqrt{a_c}} \quad (3)$$

This expression shows that the fracture strength depends linearly on the fracture toughness K_{IC} and is inversely proportional to the square root of the critical flaw size a_c . It also shows that there are two ways to improve the strength of dental ceramics, either by increasing the fracture toughness which is a true material property and/or controlling the defect size which is more processing-related.

The strength of ceramics is often determined in a bending test. Tensile testing of ceramics and glasses is rarely done due to the high expense of specimen fabrication and the difficulties of performing tensile tests without introducing bending stresses and damaging contact stresses during gripping. Compressive stresses of ceramics are often reported but ceramics rarely fail under compressive stresses. The fracture strength of dental ceramics can be measured by four-point bending, three-point bending and biaxial strength testing of rectangular specimens according to the ISO, 6872:2015 standard (ISO, 6872, 2015). The probability of finding a large defect is higher in a larger specimen and the average strength of larger ceramic specimen is therefore lower than that of smaller specimens. Surface machining and contact damage can induce critical defect on the surface. The measured fracture stress varies as well with the specimen shape. Since the size and location of the critical defect in each ceramic specimen can be different, the strength of a batch of ceramic specimens generally has a large scatter. Under these conditions, one might wonder whether a specific dental prosthesis made from a certain dental ceramic will indeed have the reported strength. The reported strength typically represents the average value and the standard deviation of a range of strength data, while a strength probability analysis is necessary to describe and design dental ceramics. The statistic nature of the strength of ceramics components can be treated by Weibull statistics. Weibull analyses are based on the weakest link hypothesis which assumes that flaws in the specimen do not interact with each other (Danzer, 1992). The two-parameter Weibull distribution that is generally used for the strength of dental ceramics can be described as (ISO, 6872, 2015):

$$P_f = 1 - \exp \left[- \left(\frac{\sigma}{\sigma_0} \right)^m \right] = 1 - P_s \quad (4)$$

where P_f is the failure probability which can be determined by $P_f = i - 0.5/N$ with i = rank in strength and N = number of specimens in the batch. P_s is the survival probability. m is the shape parameter or Weibull modulus and σ_0 is the characteristic strength, a scaling parameter at which $P_f = 1 - \exp(-1) \approx 63.2\%$. Fig. 2 shows a typical Weibull distribution plot of a zirconia ceramic for illustrative purposes.

The Weibull plot can be used to determine the failure or survival probability of a sample under a given load with the specific shape, size and processing conditions for which the Weibull plot was generated. In addition to the mean and characteristic strength, the Weibull modulus can be used as a factor in the design of dental restorations that are made from brittle ceramics. For example, if a dental application specifies that 2% ceramic restoration failures can be accepted, the strength data can be tested and

Fig. 2 Weibull diagram of failure probability versus strength for the four-point bending strength measured on a 3 mol% yttria-stabilized zirconia. The axes are scaled to represent the Weibull distribution as a straight line and the slope of $\ln \ln (1/(1-P_f))$ versus $\ln \sigma$ is the Weibull modulus (m). Dashed lines indicate the borders of the combined 95% confidence intervals.

Weibull analysis can be used to estimate the stress level that matches this 2% failure rate in order to optimize the design or the dimensions of restorations and/or restricting the conditions of use so that no location within the restoration would be loaded above the failure stress. Another important parameter is the Weibull modulus (m), which depends on the flaw distribution in ceramics and indicates the scatter of the strength data. A high Weibull modulus reflects a low variation in measured strength values and a reduced probability that flaws will interact to weaken a brittle material. Engineered ceramics typically have a Weibull modulus of 5–20, whereas ductile metals such as aluminum can have a high m value of about 100 (Lambrigger, 1997; Gong *et al.*, 2020; Meyers and Chawla, 2008).

A large number of specimens needs to be tested in order to determine accurate values for the Weibull parameters (Weibull modulus and Weibull scale parameter, i.e., characteristic strength), especially for the Weibull modulus (Davies, 2017). ISO 6872 requires to prepare at least 10 and preferably 30 specimens, but usually a minimum of 30 samples is required to obtain an acceptable estimation precision of the Weibull modulus (Wu *et al.*, 2001; Davies, 2017). It can be observed from Fig. 3 that the confidence intervals of the Weibull modulus get rapidly narrower with increased specimen number, especially for $n < 30$. A sample number of about 30 is the turning point of gaining the precision and, when the sample size is higher than 100, the difference in gaining more precision become small with a confidence of higher than 90% (McLean and Hartsock, 1989).

Although the Weibull modulus of strength data obtained under fast fracture conditions can be used to determine the reliability and fracture probability of ceramics over time, other factors such as cyclic loading and environmentally-assisted subcritical crack growth can occur in dental ceramics. Existing cracks may propagate subcritically under external loads, resulting in a “time-dependent” strength and affecting the reliability of dental ceramic components. Therefore, it would be more useful if the data for Weibull analysis are obtained under test conditions that closely simulate clinical conditions, including cyclic fatigue and oral fluid conditions.

Strength and Toughness of Dental Ceramics

The International Organization for Standardization (ISO) provided the recommended values of flexural strength and fracture toughness for ceramic dental prostheses and restorations with respect to their intended clinical use, as specified in ISO, 6872:2015 and recalled in Table 2. The flexural strengths of different dental ceramics are shown in Fig. 4 and the fracture principles introduced above are valid for all these materials. It is clear that the mechanical properties of dental ceramics vary over a wide range with a strength from 60 MPa to more than 1000 MPa (Zhang *et al.*, 2019). Along with the required mechanical properties, the clinical use of different dental ceramics is also guided by the optical properties of the dental ceramics itself with high translucency being emphasized as one of the primary parameters in controlling optical appearance. It is widely known that the ceramics having better esthetics/translucency in general are less strong, and vice versa (see Fig. 5). Glass-ceramics are more brittle but more translucent and are normally used in low load-bearing areas, whereas polycrystalline ceramics are stronger and tougher but more opaque and typically used in posterior highly stressed areas. In recent years, ceramic dental implants are attracting more and more interest as well but only zirconia ceramics and zirconia-based ceramic composite materials fulfill the mechanical requirements to be used as dental implant and abutment, as specified in ISO 13356. More details are summarized in Tables 2 and 3 shows the general mechanical properties and indications for use of various dental ceramics.

Ceramics With a Glass Phase

Feldspathic porcelain is made from molten mixtures of pure natural feldspars. Its amorphous structure consists of a disordered network of polymer-like chains made of silica tetrahedra linked together by sharing common oxygen atoms (Kelly, 2008). Feldspathic porcelains with predominantly glass phase are very brittle with low strength, limiting their use to low-stress applications. Many efforts have been made to add filler particles to the base glass composition to improve the mechanical properties. The fillers can be crystalline but also particles of high-melting glasses that are stable at the sintering temperature of the ceramic material. If the ceramic particles are formed by a precipitation process through a nucleation and growth heat treatment, the materials are referred to as glass-ceramics, like leucite (KAlSi_2O_6) reinforced glass-ceramics and lithium (di)silicate ($\text{Li}_2\text{Si}_2\text{O}_5$ or Li_2SiO_3) glass-ceramics. The strength enhancement in leucite reinforced glass-ceramic is attributed to a good dispersion of the fine leucite crystals as well as the tangential compressive stresses that are developed around the crystals upon cooling because of the difference in coefficient of thermal expansion (CTE) between leucite crystals and glassy matrix. As such, crack deflection becomes an active toughening mechanism improving the toughness and strength (Denry *et al.*, 1996; Fu *et al.*, 2020; Apel *et al.*, 2008). Regarding lithium (di)silicate glass-ceramic, as compared to leucite reinforced glass-ceramic, a larger fraction (up to 70%) of

Fig. 6 (a) Leucite reinforced glass-ceramic (IPS Empress[®] CAD, Ivoclar Vivadent AG) shows lamina-like, irregular-shaped leucite crystals. Surface was etched with 3% HF for 10 s (b) Interlocked microstructure of lithium disilicate glass-ceramic (IPS e.max[®] CAD, Ivoclar Vivadent AG). The glass phase has been removed by acid etching with 40% HF vapor for 30 s, leaving needle-like lithium disilicate crystals. Adapted from Ritzberger, C., Apel, E., Höland, W., *et al.*, 2010. Properties and clinical application of three types of dental glass-ceramics and ceramics for CAD-CAM technologies. *Materials* 3, 3700–3713.

cross-linked fine rod-like elongated crystals are used to reinforce the glassy matrix and multiple crack deflections are attributed to an improved crack resistance and concomitantly higher strength and toughness (Zhang *et al.*, 2019; Ritzberger *et al.*, 2010; Fu *et al.*, 2020; Apel *et al.*, 2008; Belli *et al.*, 2018) (Fig. 6). Glass-infiltrated ceramics consist of a porous pre-sintered ceramic core that is infiltrated with a low-viscosity lanthanum aluminosilicate glass fired at 1100°C for 4–6 h to eliminate porosity and increase strength. In-Ceram[®] glass-infiltrated oxide materials are available in three variations subsequently veneered with an esthetic porcelain: a spinel core, an alumina core, or an alumina-zirconia core and all of them are primarily crystalline with successively increasing bending strength and decreasing translucency. Glass-infiltrated oxide ceramics are nowadays no longer used in dentistry.

Polycrystalline Oxide Ceramics and Ceramic Composites Without Glass Phase

Alumina was early introduced in dentistry and has been subjected to continuous development processes. The main effort to improve its strength from less than 400 MPa to more than 600 MPa was achieved by defect-control, e.g., proper selection of raw materials, powder processing, sintering, etc. However, alumina is still quite brittle without very efficient toughening mechanisms. Since the introduction of tougher and stronger zirconia ceramics, pure alumina is no longer used as dental ceramic. In very recent years, a lot of effort is given to produce bioinspired alumina-based materials using platelet-shaped alumina particles. Nacre-like “brick-and-mortar” structures have been successfully fabricated (Munch *et al.*, 2008; Bouville *et al.*, 2014; Le Ferrand *et al.*, 2015), giving rise to a remarkable crack resistance (fracture toughness above 20 MPa m^{1/2}, 7 times higher than the toughness of typical alumina ceramics).

Zirconia ceramics, in particular 3 mol% yttria-stabilized tetragonal zirconia polycrystalline (3Y-TZP) ceramics can have a fracture toughness of 5–8 MPa m^{1/2} and a flexural strength of 900–1400 MPa, the highest ever reported for any dental ceramic, enabling the fabrication of multi-unit FDPs for stress-bearing posterior dentition. Pure zirconia is a polymorphic material that occurs in three different forms depending on temperature: monoclinic (m) at room temperature, tetragonal (t) above 1170°C, and cubic (c) beyond 2370°C. The phase transitions are reversible and accompanied with a volume expansion of about 0.5% in the case of the c to t transformation and about 4% for the t to m transformation. Furthermore, zirconia can be stabilized at room

temperature as cubic and/or tetragonal polymorph, depending on the stabilizer type (CaO, MgO, Y_2O_3 , CeO_2 , etc.) and their quantity (Kelly and Denry, 2008). If transformable tetragonal phase is present within a matrix of cubic zirconia, one refers to partially stabilized zirconia (PSZ). If zirconia is fully tetragonal, one refers to Tetragonal Zirconia Polycrystals (TZP). The most interesting property of zirconia ceramics originates from the fact that tetragonal zirconia is metastable at room temperature and can be transformed to a stable monoclinic phase by shear and/or hydrostatic tensile stresses. When a crack propagates, the concentrated tensile stress field at the crack tip enables t-m transformation and the associated volume expansion generates localized compressive stresses which act against the applied stress intensity factor and inhibit crack propagation (Hannink *et al.*, 2004). This process can significantly increase the toughness of zirconia ceramics due to an enhanced crack growth resistance (i.e., R-curve behavior), see Fig. 7.

Among the different zirconia ceramics, yttria-stabilized tetragonal zirconia polycrystals that normally contain 3 mol% yttria (3Y-TZP) are today the benchmark materials for dental clinical applications due to their high strength, fine grain size and good wear properties. They are recommended for framework materials in porcelain-veneered crowns and FDPs in posterior and anterior regions. 3Y-TZP has also been promoted as an alternative for titanium implants and abutments due to the natural coloration, higher wear and corrosion resistance, improved biocompatibility and lower affinity to bacterial plaque and peri-implantitis (Pieralli *et al.*, 2017). When compared to alumina, not only the higher bending strength and fracture toughness, but also the lower hardness and elastic modulus of zirconia are more attractive for use in dentistry. While dense alumina has a hardness of about 16 GPa, the hardness of Y-TZP is lower, which is a clear advantage in the adjustment of coronal parts by machining. Another advantage of zirconia over alumina is the substantially lower elastic modulus (200 GPa versus 380 GPa), which implies lower elastic stresses between the natural dentine and the prosthetic work.

However, classic dental 3Y-TZP that normally contains 0.25 wt% alumina is relatively opaque and needs to be veneered with a quite thick layer of feldspathic porcelain in order to meet the patient's individual tooth characteristics. The trend towards monolithic ceramic restorations, in order to avoid the difficulties with the veneering ceramics, i.e., the clinically rather regularly encountered chipping of bi-layered zirconia ceramics (zirconia substrate with veneering top layer), has requested zirconia ceramics to be more translucent. Therefore, several generations of more translucent yttria-stabilized zirconias have been introduced in dentistry, either based on a reduced light-scattering alumina content to as low as 0.05 wt% and/or increased yttria content. Partially stabilized zirconia (PSZ) containing 4–6 mol% yttria however have a lower toughness, strength and reliability (see Fig. 8) due to a reduced transformability with increased non-transformable cubic ZrO_2 content and less-transformable tetragonal zirconia (Zhang *et al.*, 2019; Zhang and Lawn, 2018; Zhang *et al.*, 2020b) and faster crack growth. It is also noteworthy that although zirconia stabilized with 3 mol% yttria is referred to as 3Y-TZP, it in fact is a mixture of *t*- and about 15 wt% *c*- ZrO_2 .

Nevertheless, zirconia transformation toughening can be exploited to improve the mechanical properties of ceramics in different ways, in particular in alumina toughened zirconia (ATZ) composite materials. In contrast to orthopedics, ceramic composites have not yet found much applications in dentistry, probably because such a ceramic composite is opaque and thus not appreciated from an esthetic point of view. One alumina-zirconia composite was however already introduced in dentistry, i.e., NANOZR® (Panasonic Electric Works, Osaka, Japan). It is a nanocomposite based on the research of Nawa *et al.* (1998). The optimized material consists of 10 mol% Ce-TZP matrix and 30 vol% of alumina, and characterized by an interpenetrating microstructure, in which nano-sized alumina grains are trapped inside the zirconia grains. NANOZR® ATZ has a comparable strength as 3Y-TZP, but a higher fracture toughness (Table 3) and higher resistance to slow crack growth under static and cyclic loading conditions (De Aza *et al.*, 2002).

Slow Crack Growth (SCG) and Fatigue

In the section above, we focused on the basic mechanical properties of brittle ceramics, as measured on specimens tested at a fast rate assuming that fracture would occur after the application of a load. This is appropriate since standards for dental ceramics solely require minimum mechanical properties that are measured under fast fracture conditions. However, this should not be

Fig. 7 Illustration of the transformation toughening effect and crack resistance (K_R) as a function of the crack extension (Δa). h is the transformation zone width and transformation toughness enhancement (ΔK_{CT}) is proportional to $h^{1/2}$.

Fig. 8 Weibull plot with 95% confidence bands for the four-point bending strength of zirconia ceramics stabilized with 3 mol% (3Y), 4 mol% (4Y) and 5 mol% (5Y) yttria. The characteristic strength (failure probability of 63.2%) is marked by the horizontal line. Reprinted from Zhang, F., Reveron, H., Spies, B.C., *et al.*, 2019. Trade-off between fracture resistance and translucency of zirconia and lithium-disilicate glass ceramics for monolithic restorations. *Acta Biomaterialia* 91, 24–34. Fig. 9 The different crack growth velocity regions observed in $V-K_I$ curves. Region 0 is the safe region. Region I (low V) is strongly influenced by the reaction between the ceramic and the corrosive environmental species. Region II (intermediate V) is much less sensitive to K_I . Region III (high V) is associated with fast fracture and corresponds to the commonly reported fracture toughness (K_{IC}). Adapted from De Aza, A.H., Chevalier, J., Fantozzi, G., *et al.*, 2002. Crack growth resistance of alumina, zirconia and zirconia toughened alumina ceramics for joint prostheses. *Biomaterials* 23, 937–945. Chevalier, J., Olagnon, C., Fantozzi, G., 2004. Subcritical crack propagation in 3Y-TZP ceramics: Static and cyclic fatigue. *Journal of the American Ceramic Society* 82, 3129–3138. Copyright (2002), with permission from Elsevier.

considered sufficient for safe use in patients, since the humid environment and cyclic loading in the oral environment can degrade the restoration load-bearing capacity over time (Ritchie, 1999; Lawn, 2010).

Chemically-assisted slow crack growth or subcritical crack growth (SCG) occurs due to the presence of water molecules (or other corrosive species, like ammonia or polar solvents). This process is known as static fatigue, which promotes breakage of the strained ionic-covalent bonds at the crack tip or any pre-existing defect due to a stress corrosion reaction, and initiates crack propagation at stress intensities (K_I) below the material fracture toughness (K_{IC}) (Chevalier *et al.*, 2004; Lawn, 2010). The

relationship between the crack growth velocity (V) and the stress intensity factor (K_I) can be used to describe the susceptibility of ceramics to SCG (Chevalier *et al.*, 2004; Lawn, 2010; Swain, 2014). Fig. 9 shows a schematic of a V - K_I diagram which features four (0, I, II and III) different stages with distinct mechanisms for a given environment. In each stage, a power law ($V = \alpha K_I^n$) can fit the speed at which cracks propagate when stressed, where α and n are constants dependent on the material properties and environmental variables. If the crack propagation parameters (α and n) are known for each stage, it is possible to estimate the durability or lifetime of a component. Furthermore, the presence of a threshold (K_{I0}) in the stress intensity factor provides the basis for the safety design of a load-bearing material. The threshold (K_{I0}) corresponds to a crack equilibrium below which no crack propagation will occur, representing a more intrinsic toughness property than the widely used fracture toughness (i.e., critical stress intensity factor), K_{IC} . The higher the K_{I0} threshold, the higher the reliability and consequently longer lifetime. Moreover, a higher slope of the V - K_I/K_{IC} curve indicates that the ceramic is less sensitive to time-dependent failure, as SCG occurs under larger applied K_I/K_{IC} values. Considering the fact that the oral cavity is a complex environment with a fluctuating temperature, high acidic environment (low pH), bacteria, etc., SCG which results from the combined effect of high stresses at the crack tip and the presence of water molecules that induce crack propagation in a subcritical manner can be important for dental ceramics. Fig. 10 shows the V - K_I diagrams measured by the double torsion method under static and cyclic loading conditions for two currently popular dental ceramic systems, namely lithium disilicate and zirconia ceramics with different translucency levels. This shows that dental ceramic materials are indeed susceptible to slow crack propagation at K_I values below K_{IC} . Independent on the K_{IC} and yttria content, zirconia stabilized by different yttria contents show a similar relative susceptibility to SCG under static loading (parallel shift of V - K_I curves), while having a significant higher SCG resistance than lithium disilicate glass-ceramic ($K_{I0,static}/K_{IC}$ of lithium disilicate

Fig. 10 Slow crack growth: (a) V - K_I curves under static loading in air for lithium disilicate glass-ceramic (LS_2 , IPS e.max CAD) and three high-translucent zirconia ceramics (3Y, 3 mol% yttria-stabilized tetragonal zirconia; 4Y, 4 mol% yttria-stabilized zirconia; 5Y, 5 mol% yttria-stabilized zirconia). The different crack-velocity regions (stage III, stage II, stage I and stage 0, i.e., threshold K_{I0}) are marked in the 3Y curve. (b) Effect of cyclic loading (10 Hz, $R = P_{min}/P_{max} = K_{I,min}/K_{I,max} = 0.1$) on V - K_I curves of the three zirconia ceramics, presented as V - $K_{I,max}$. The black dashed line represents the estimated V - $K_{I,max}$ curve if there would be no cyclic degradation in 3Y. (c) Comparison of V - $K_I/K_{I,max}$ curves of 5Y zirconia and LS_2 glass-ceramic under static and cyclic fatigue. Reprinted from Zhang, F., Reveron, H., Spies, B.C., *et al.*, 2019. Trade-off between fracture resistance and translucency of zirconia and lithium-disilicate glass ceramics for monolithic restorations. *Acta Biomaterialia* 91, 24–34. glass-ceramic ~ 0.4 smaller than that of zirconia ceramics). The ceramics with glass phases are indeed generally more susceptible to SCG than polycrystalline ceramics without a glass phase (Borba *et al.*, 2011; Wendler *et al.*, 2018; Olagnon *et al.*, 2006; Gonzaga *et al.*, 2011).

Moreover, in addition to the chemically-assisted SCG, mechanical fatigue by cyclic loading is also important (Zhang *et al.*, 2013). In general, cyclic loading lowers the load-bearing capability and accelerates crack growth in brittle ceramics by degrading the extent of crack-tip shielding toughening mechanisms (Ritchie, 1999). These can involve transformation toughening, crack bridging, crack deflection or combinations thereof (Launey and Ritchie, 2009). Fig. 10 illustrates that the crack growth rates under cyclic loading are accelerated with smaller K_{I0} as compared to static crack growth at equivalent stress intensities, independent on the ceramic type and toughening mechanisms. Furthermore, in addition to the flexure load as shown before in Fig. 1, contact damage is of great importance for dental restorations as well. Although the contact stresses at the surface are mainly compressive during chewing activity, tensile stresses can locally occur especially by biting on a hard object with large curvature. Various damage modes are identified in clinically fractured crowns and bridges, and different types of cracks including radial cracks, cone cracks and edge chipping cracks may initiate from the contact zone at the occlusal surface, at the cementations surface as well as from the margins (Fig. 11) (Zhang and Lawn, 2019; Zhang *et al.*, 2013). These damages maybe not be deep, but they are cumulative and can act as a failure origin especially under cyclic fatigue conditions for both veneered and monolithic restorations. Contact testing using sphere indenters on flat specimen is proposed to simulate occlusal and intaglio damage (Zhang and Lawn, 2019). Fig. 12

Fig. 11 Various damage modes in ceramic crown at occlusal and cementations surfaces from axial, sliding and edges contacts. Reprinted from Zhang, Y., Lawn, B.R., 2019. Evaluating dental zirconia. *Dental Materials* 35, 15–23. Copyright (2019), with permission from Elsevier.

Fig. 12 Strength of 3Y-TZP zirconia after occlusal damage from cyclic contacts with sphere of 3.18 mm radius in water under axial and sliding loading. Data points for specimens on the lower solid lines are failures from contact sites. Boxes at left axis are strengths of un-indented specimens (standard deviation bounds). shows the remaining strength of 3Y-TZP zirconia ceramics after cyclic contact at the occlusal surface with sphere indenter of 3.18 mm radius under axial and sliding loads in water condition. Importantly, the strength degradation is larger for sliding loading condition after a relatively small numbers of cycles and at a much lower contact load than that for axial loading condition, due to the accumulation of surface attrition and the formation of macroscopic cracks in quasi-plastic mode (Zhang and Lawn, 2019; Jung *et al.*, 2000). The strength degradation is determined by the numbers of cycles but not by the contact time, emphasizing the importance of mechanical fatigue (as opposed to time-temperature chemically-assisted SCG) for dental ceramics especially for relatively tougher ceramics (Zhang *et al.*, 2013; Kim *et al.*, 1999). Fatigue tests using clinically relevant ceramic configurations that take the contact cyclic loading, SCG and environment into consideration are needed to better predict the lifetime of dental ceramics. With respect to the fatigue testing of dental zirconia implants, ISO standard 14801 addresses the topic but it is mainly dedicated to titanium-based implants. An experimental setup for a dynamic fatigue procedure is prescribed and it is required to cyclic fatigue test the final market-ready product with an angulation of 30° to the vertical axis along with a simulated alveolar bone recession of 3 mm (ISO 14801, 2017). However, other environmental factors like hydrothermal aging are not considered. ISO 13356 examines the hydrothermal aging of standardized bending bars with polished surface zirconia test specimens subjected to humidity at 134°C and 0.2 MPa for 5 h. The adaption and combination of both ISO 14801 and ISO 13356 standards using a chewing simulator can be proposed as laboratory test to check a priori the reliability of zirconia implants (Zhang *et al.*, 2020a).

Conclusions

Dental ceramics comprise a wide variety of materials ranging from glasses to dense polycrystalline ceramics with properties varying over a broad range and there is no single material perfectly suited for all clinical applications. This chapter tried to introduce the mechanical properties of different dental ceramics. Their initial strength and toughness are summarized to guide the choice of the most appropriate material for a specific clinical requirement. Since dental ceramics fracture in a brittle way with a large scatter in strength values, the strength distribution needs to be statistically approached to assess the material reliability. On the other hand, cracks or preexisting flaws in ceramics may subcritically and slowly propagate under a load that is lower than the fracture strength, lowering the load-bearing capability of dental ceramics over time and resulting in a “time-dependent” strength. Chemically-assisted slow crack growth, hydrothermal aging and fatigue testing need to be considered to design the dental ceramics, preferably under testing conditions that closely mimic the clinical application.

Biological Assessment of Bioceramics: In Vitro and In Vivo Tests

Maria H Fernandes and Pedro de Sousa Gomes, Faculty of Dental Medicine, BoneLab, U. Porto, Porto, Portugal and LAQV/REQUIMTE, U. Porto, Porto, Portugal

© 2021 Elsevier Inc. All rights reserved.

Bioceramics are biocompatible materials widely used in the mineralized tissues, with proven usefulness in replacement and regeneration strategies. Inert bioceramics (e.g., alumina and zirconia) are unable to induce an interfacial behavior with the host tissue, being encapsulated by a thin layer ofacellular collagen at the tissue interface. Otherwise, bioactive bioceramics (e.g., hydroxyapatite, tricalcium phosphate, bioglasses, and ceramic composites) are actively involved in interfacial events with complex ionic, molecular and cellular underlying mechanisms, ultimately leading to a direct chemical bonding with the surrounding tissues. Active bioceramics may present themselves with varying degrees of bioresorbable behavior, with an active role in the bone metabolic activities, being progressively partial or completely replaced by the host tissue (Ginebra *et al.*, 2018).

Bioactivity is closely related with the chemical and physical properties of the material itself but is greatly modulated by the processing route, sterilization process, presentation form (bulk, particulate, 3D scaffolds) and porosity (dense, porous), endowing the prepared material sample with a different physic-chemical profile. More advanced strategies involving the addition of physiological relevant biomolecules and cells, may further tailor the bioactivity to elicit specific tissue responses for particular clinical settings.

In most repair and regenerative approaches, the bioceramic is set up to remain in the implanted bone for a long period. Studying the initial tissue interactions and the later biological behavior, usually progressing to a steady state that ensures the continuous performance of the material, is a lengthy and challenging task. This is expected, taking into account that a bioactive material is implanted in a complex and highly dynamic tissue undergoing constant modeling and remodeling activities.

The development of bioactive ceramics with endless possibilities for modulating and tailoring their bioactivity demands mandatory evaluation of the biological response to ensure material safety and efficacy. This follows progressively complex in vitro and in vivo approaches, prior moving to clinical trials and marketing. This chapter summarizes the commonly used in vitro and in vivo methodologies to assist in the biological evaluation of a biomaterial targeted for bone replacement and regeneration. For a better understanding, basic concepts of the bone metabolism and bone tissue/material interaction are also briefly considered.

Bone Tissue-Biomaterial Interaction

Bone is a connective tissue consisting of a calcified extracellular matrix (~90%) and a cellular component (~10%). Cortical bone, heavy mineralized (up to 80% of the skeleton), forms the outer layer of bones, while the inner parts contain trabecular bone imbibed in marrow (Teti, 2011). The bone matrix is a composite component. Around 60% is mineralized by the presence of calcium phosphate in the form of hydroxyapatite, $(\text{Ca}_5[\text{PO}_4]_2\text{OH})$, and the organic component is mostly collagen type I (85%–90%), including also non-collagenous proteins (~10%), lipids and glycosaminoglycans. The matrix is permeated with a well-organized network of osteocytes, terminally differentiated osteoblasts, while the quiescent bone surfaces are covered by a monolayer of bone lining cells (also, osteoblastic lineage cells). Bone is continuously being remodeled by the concerted actions of the bone resorbing osteoclasts and the bone forming osteoblasts. Together, the inorganic and the organic content, and also the structural organization in cortical and trabecular bone, give the tissue its performance in resisting torque, compression and shear stress (Teti, 2011).

Bone modeling and remodeling are highly regulated by a complex interplay of local and systemic modulators, involving autocrine, paracrine and endocrine mechanisms translated through key intracellular signaling pathways. Bone modeling is an unbalanced process in which bone resorption and bone formation can occur independently to allow harmonic growth and adaptation to mechanical loading (Langdahl *et al.*, 2016). Conversely, bone remodeling is a homeostatic renewal process, in which the resorption of old or damaged bone is coupled, spatially and temporally, to the formation of the same amount of new bone. Each year, approximately 5% of cortical bone and 20% of trabecular bone are remodeled ensuring metabolic homeostasis and functional integrity. Additionally, bone is a source of a variety of molecules involved in local and systemic metabolic activities, as calcium and phosphate homeostasis, kidney function and energy metabolism, being thus considered an endocrine organ.

Bone tissue deals with the implanted biomaterial as a foreign body, triggering multi-directional, temporal and spatial immune responses, hopefully leading to positive outcomes on the biomaterial integration and long-term stability. This process involves three key players – the material, the immune system mediators and cells, and the bone cells (Franz *et al.*, 2011; Chen *et al.*, 2016).

Immediately after implantation, proteins from surrounding blood and interstitial fluids (e.g., fibrinogen, complement proteins, vitronectin, and fibronectin) adsorb to the material surface within seconds forming a transient surface matrix. This elicits the activation of the coagulation cascade and the complement system, ending up with the formation of a thrombus. Simultaneously, an acute inflammatory reaction is set up involving the recruitment and the activation of neutrophils and other polymorphonuclear leucocytes that release proteolytic and reactive oxygen species, attempting to degrade the material. After a short time (~two days), these initially recruited inflammatory cells undergo apoptosis. Following, degranulation of activated mast cells release pro-inflammatory cytokines

and other mediators amplifying the immune reaction. This paracrine environment promotes the recruitment of monocytes and their differentiation into macrophages, with also a rich cytokine pattern release. These events are accompanied by the revascularization of the injured tissue, ensuring the availability of nutrients, immune and bone precursor cells, bioactive molecules and, also, the removal of the waste products resulting from the intense cellular and molecular activity.

Simultaneously to this host response, the material can also have a dynamic behavior, a process related to its bioactivity. In contact with the body fluids and the local acidic environment elapsing from the inflammatory process, bioactive bioceramics release calcium and phosphate ions (and other ions, depending of the chemical composition) and even material debris to the surroundings. The interacting host response (with plenty of bioactive molecules) and material surface reactivity (associated to the on-going dissolution/precipitation events) lead to a progressive surface conditioning, which can positively modulate the recruitment, adhesion and differentiation of osteoblastic precursors. As a result, differentiated osteoblasts on the material surface produce an immature bone tissue, which later undergoes remodeling by the concerted action of osteoblasts and osteoclasts. Through all these events, some initially entrapped bioactive bioceramics are further degraded being partial or totally replaced by bone. Constant remodeling, driven by functional loading and mechanical strain, sensed by the osteocyte communication system in the mineralized matrix, ensures the long-term metabolic and functional performance of the regenerated tissue (Ginebra *et al.*, 2018).

In Vitro Cell Culture Models for Bioceramics' Biological Characterization

In vitro testing of bioceramics involves the use of cell culture systems that attempt to be representative of the bone metabolic cellular and molecular activities. However, bone is a rather complex tissue encompassing a dynamic interaction of several cell types and a mineralized collagenous matrix, to cope with the constant and variable mechanical load associated to locomotion. Trying to recreate the bone physiology in vitro is a challenging task, never fully achieved. As such, cell culture systems are constantly being improved to better accomplish more representative models (Scheinplug *et al.*, 2018). Nevertheless, relatively basic methodologies continue to be routinely used providing relevant information, as long as they are focused on specific objectives.

In vitro models aim to provide information on the cytocompatibility and specific bone cells' functionality upon contacting with the material. As normal bone metabolism encompasses dynamic events of bone formation and bone resorption, the material performance is usually evaluated through the response elicited in the behavior of osteoblastic and osteoclastic cells. Single-cell culture systems evaluate the response of each of these cell types associated to the interfacial cellular and molecular events and underlying intracellular mechanisms. However, the complex and reciprocal cellular interactions occurring during normal bone remodeling are not analyzed. Co-culture systems of bone cells, particularly involving osteoblasts and osteoclasts, are required to evaluate such behavior. Single-cell cultures or co-cultures are routinely established in 2D conditions. In this setting, cells are seeded directly on the bioceramics or they are exposed to the materials' extracts/leaching products. These models lack the tridimensional nature of the cell-to-cell and cell-matrix interactions. Several 3D cell culture methodologies are described, and continuously improved, to better elucidate the material/bone cells/matrix interactions (Scheinplug *et al.*, 2018). Bioceramics in particulate form might be analyzed in scaffold-free 3D spheroid cultures that can be generated from a mixture of the particles and single or multiple bone cells. This system evaluates relevant interactions in a 3D environment. Porous bioceramic scaffolds naturally provide a 3D environment for in vitro testing (Laranjeira *et al.*, 2009; Meurice *et al.*, 2016). Further, both 2D and 3D models are also able to incorporate dynamic flow conditions using bioreactors with varying degrees of complexity and, additionally, allow mechanical loading during cell/material culturing (Owen and Reilly, 2018).

The selection of the cell system, i.e., cancerous or immortalized cell lines versus primary cells, is obviously relevant, being targeted to the research purpose (Czekanska *et al.*, 2012). Cell lines have several advantages, mainly related to the high expansion potential and reproducibility. They also express several molecular and functional markers of normal cells. As such, these cells might be quite useful to screen large amounts of material samples (bulk, particulate), providing rapid and reproducible feed-back information in the different stages of the material development process. As the major limitation, they do not express a normal phenotypic differentiation. As such, cell lines/immortalized cells normally display a behavior associated with certain stages of the phenotypic development. In some contexts, this turns up to be useful, helping in the characterization of the underlying mechanisms elicited by the biomaterial in the different stages of phenotype development, assisting in targeted research objectives. However, the non-physiological behavior of the cell lines raises concerns regarding translational value of these systems (Czekanska *et al.*, 2014).

Animal and human primary cells constitute the most adequate tool for having more representative models, as they are able to display the complete phenotypic differentiation behavior. Animal (mostly, rat and mouse) bone cell cultures are frequently used and main advantages include accessibility, various collection locations and control of the donor animal in terms of age, weight and gender. Rat bone cells are very useful in some research settings, due to the known genome with the availability of all genetic and molecular tools to analyze the mechanisms underlying the elicited biomaterial response (Czekanska *et al.*, 2012). However, due to inter-species differences, human primary cells provide more representative models (Czekanska *et al.*, 2012, 2014). Limitations are associated with the availability of biological samples for culture establishment, sampling locations and reproducibility of cell behavior, due to donor-related variability (age, gender, health status, medication, etc.).

The culture medium and the culture time are crucial in cell culture testing (Yoshimura *et al.*, 2017). Several standardized media are available to feed single-cell cultures. Even so, there is a great variability in media composition, mainly due to the addition of varying targeted supplements. The culture time should be settled according to the research purposes, i.e., to analyze specific cellular interfacial events, and it varies greatly. This scenario is further complicated for co-cultured cells (Zhu *et al.*, 2018). Each cell type has

specific in vitro growth needs and distinct temporal differentiation processes. Also, the reciprocal direct-contact/paracrine interactions influencing both cell types need to be considered for appropriate and representative in vitro systems, might also hamper results comparison and the translational usefulness of these systems.

Bioactive bioceramics are characterized by a high surface reactivity when in contact with the aqueous biological environment, forming a strong bonding with the bone tissue. In vivo, due to the continuous fluid flow, the initial burst ion release (calcium and phosphate ions, other ions present in the material composition) is soon followed by a dynamic ionic exchange at the material/fluid interface, with dissolution/precipitation events, leading to the formation of a biological-like hydroxyl-carbonate-apatite layer, similar to the mineral phase of the bone. This apatite layer also contains bioactive molecules precipitated from the surroundings, during these exchange events. These favored conditions allow for cell adhesion, proliferation and differentiation of bone cells, resulting in strong bonding with the bone tissue (El-Rashidy *et al.*, 2017). In vitro, in the static cell culture environment, the high surface reactivity of some bioceramics is problematic. For high reactive bioceramics, the initial burst ion release results in a high ionic concentration in the material surface vicinity, with relevant changes in the pH and the osmotic conditions, creating a localized cytotoxic microenvironment that prevents cell adhesion and/or causes cell death (Dias *et al.*, 2005). To overcome this, preconditioning the material prior to cell seeding is routinely used. Establishing the appropriate protocol is challenging, as it depends on the material composition, surface features and formulation.

Preconditioning consists in the immersion of the material sample, for a certain period, in an aqueous solution, before cell seeding. Media frequently include TRIS buffer, an organic buffer solution, simulated body fluid (SBF), with similar ion concentration to that of human plasma, and commonly used culture media, i.e., Alpha Minimum Essential Medium (α -MEM) and Dulbecco's Modified Eagle's Medium (DMEM), supplemented or not with serum. The preconditioning protocol might be performed in one step or two steps (using the same or a different immersion medium), and with or without medium refreshing. Preconditioned surfaces are more cytocompatible due to the already stabilized ion release together with the formation of an apatite-like layer, favoring cell adhesion, proliferation and differentiation. A comprehensive review on this issue was recently published (Ciraldo *et al.*, 2018). Performing the cell culture studies in dynamic fluid flow conditions further allows a continuous dilution of the released species, being more representative of the in vivo conditions (Karadjian *et al.*, 2019).

The Osteoblast and Bone Formation – In vitro Models

The osteoblasts are present in the active bone remodeling surfaces, being in charge for synthesizing the extracellular organic matrix and assisting in its mineralization. Mature osteoblasts are basophilic, mononuclear and polygonal cells and exhibit the features of a protein-producing cell, i.e., well-developed rough endoplasmic reticulum, prominent Golgi complex and chromatic nucleus with large nucleolus.

Osteoblasts originate from pluripotent mesenchymal stem cells (MSCs) recruited from neighboring microenvironment. Development of the osteoblast phenotype involves a complex spatial-temporal endocrine, paracrine and autocrine regulation, with a variety of hormones and a large number of growth factors and cytokines being engaged in this process (Hayrapetyan *et al.*, 2015; Blair *et al.*, 2017). Runx2 is the key transcription factor in the nuclear environment responsible for the commitment of pluripotent MSCs into the osteoblastic cell lineage, being the master regulator for the expression of downstream key genes, as collagen type I, alkaline phosphatase, osteopontin, bone sialoprotein and osteocalcin, at an early stage of osteoblastic differentiation (Liu and Lee, 2013). Runx2 has also a role in the expression of Osterix, a later key transcription factor essential for the final stages of osteoblast differentiation (Liu and Lee, 2013). Several pathways are involved in the osteoblast differentiation sequence. Among them, TGF- β /BMP, Wnt/ β -catenin, hedgehog (Hh) and Notch pathways play pivotal roles (Hayrapetyan *et al.*, 2015; Hojo *et al.*, 2015; Majidinia *et al.*, 2018).

Osteoblast differentiation proceeds along a temporal sequence, moving from osteoprogenitors, pre-osteoblasts, to fully mature osteoblasts. This process involves initial active cell proliferation, accompanied by the synthesis of the collagenous organic matrix (the osteoid), matrix maturation and organization (during which cell growth does not occur), and matrix mineralization. This reciprocal and functionally coupled relationship between proliferation and differentiation is tightly coupled and regulated to support normal bone formation.

In each bone forming site, osteoblasts form tight junctions and produce an organized organic matrix, a complex protein mixture, secreted in a specific order, composed mainly by collagen type I (~88%), glycoproteins (e.g., fibronectin, osteonectin, osteopontin and bone sialoprotein), γ -carboxyglutamic acid containing proteins (e.g., osteocalcin and matrix gla-protein), enzymes (e.g., alkaline phosphatase, collagenases, other proteinases), proteoglycans, proteolipids and a number of growth factors (e.g., fibroblastic growth factors (FGFs), insulin-like growth factors (IGFs), TGF- β s, BMPs). Alkaline phosphatase (ALP), an enzyme present in the plasma membrane, is expressed at the preosteoblast stage and osteocalcin is highly expressed in mature osteoblasts, being considered, respectively, early and later major osteoblastic markers. During this process, a variety of biomolecules is incorporated in the osteoid but also disseminates into the local microenvironment, having paracrine effects.

Following organic matrix maturation, mineralization is initiated in small cytoplasmic membrane vesicles rich in ALP - with a key role in the initiation of the process, by providing phosphate ions. The vesicles also contain proteins and phospholipids with calcium-binding ability, and the deposition of calcium phosphate occurs within the vesicles and, subsequently, continuous in the extra-vesicular space. Here, crystals of hydroxyapatite fill the inter-collagen fibrils' spaces of the osteoid and, upon the formation of stable mineral "critical nucleus", crystal growth becomes a faster physic-chemical driven process (Hayrapetyan *et al.*, 2015).

The half-life of the osteoblast is approximately three months and they have three destinations, namely apoptosis, becoming lining cells or being entrapped in the matrix, in lacunar spaces, converted into osteocytes.

Osteoblastic cell cultures

Animal- and human-derived primary cells, induced osteoblasts from pluripotent stem cells, and immortalized and osteosarcoma cell lines, with their associated advantages and limitations, all have been used to address the dynamic cell-bioceramic material interfacial behavior (Czekanska *et al.*, 2012, 2014; Mata *et al.*, 2015).

The human osteosarcoma cell lines MG-63 and SaOs-2, and the mouse MC3T3-E1 cell line are frequently used. MG-63 cells are arrested in the pre-osteoblast stage, constituting essentially a proliferative and poor differentiated cell population. Otherwise, SaOs-2 cells are differentiated cells, presenting high levels of alkaline phosphatase and easy matrix mineralization. MC3T3-E1 mouse cells are representative of a pre-osteoblastic phenotype being able to differentiate into mature osteoblasts. They exhibit cellular proliferation senescence (as primary cells), but inter-species differences need to be accounted, i.e., dissimilarities in the proliferation rate, temporal expression of osteoblastic markers and mineralized matrix features, compared to human primary cells (Czekanska *et al.*, 2012; Hwang and Horton, 2019). Primary animal cells (mostly, from rat and mouse) are able to display the complete osteoblastic proliferation/differentiation pathway (although, senescence occurs progressively with cell passaging). Due to species-related differences, results extrapolation to human primary cells needs to be cautious (Czekanska *et al.*, 2012).

Primary human cells replicate the development of the osteoblastic phenotype, being the more representative model to evaluate cell-material interactions (Scheinpflug *et al.*, 2018). Cultures of primary osteoblast-lineage cells might be established from several sources. Embryonic stem cells (ESCs) are pluripotent cells, highly proliferative in the undifferentiated stage, and able to undergo osteogenic differentiation. Major concerns include ethical constraints, safety issues and tight control of in vitro conditions to modulate the osteogenic behavior (Korkusuz *et al.*, 2016; Scheinpflug *et al.*, 2018). For these reasons, mesenchymal stromal cells (MSCs), that can be isolated from several adult tissues avoiding ethical controversy, are considered to be a suitable cell source for in vitro model systems (Scheinpflug *et al.*, 2018). MSCs have multi-lineage differentiation potential in vitro, are relatively easy to isolate, expand and differentiate into the osteoblastic lineage using standard cell culture techniques and, additionally, are endowed with versatile paracrine features useful to co-cultured cell models. However, they undergo rapid senescence after few passages (Geissler *et al.*, 2012). MSCs can be isolated from several sources including bone marrow, umbilical cord, adipose tissue, dental pulp, among others (Gao *et al.*, 2017). They are characterized by the common stem cells attributes, but differ in several features such as colony-forming ability, proliferation rate, multilineage differentiation potential and on the proteome and transcriptome pointing to a site-specific phenotype for MSCs (Al-Nbaheen *et al.*, 2013; Akintoye *et al.*, 2006). Regarding this, bone marrow-derived MSCs (mostly isolated from bone marrow discarded in orthopedic procedures) are the most commonly used (Gao *et al.*, 2017). In vitro, medium supplementation with dexamethasone, β -glycerophosphate and ascorbic acid favors the osteoblastic differentiation (Coelho and Fernandes, 2000; Langenbach and Handschel, 2013).

Upon seeding, cells contact immediately with the material, via the transitory protein layer formed in the material surface (coming from the serum-supplemented culture medium). The initial interactions are followed by cell adhesion and cytoplasm spreading, a process mediated by specific integrins, transmembrane proteins that interact with the protein-conditioned material surface and the cytoskeleton. This implies the proper re-organization of the F-actin cytoskeleton with the establishment of focal adhesion zones, leading to the acquisition of a cell morphology fitting on the material surface topography. This initial behavior is crucial for the subsequent cell proliferation, movement and differentiation (Carvalho *et al.*, 2018; Lasgorceix *et al.*, 2018). Characterization of the cell-material response involves a variety of parameters, from the initial interaction to the completion of the osteoblastic phenotype, based on the normal osteoblast biology, and is exemplified in Fig. 1.

Testing a biomaterial with osteoblastic cell cultures is expected to assist in selecting promising materials to be further assessed in animal models. Related to this, a multicenter review study was conducted to analyze the correlation between routinely used in vitro assays (cell adhesion, viability, proliferation; cell differentiation; mineralization assay) with the in vivo outcomes of bone regeneration in early stage (small animal) models, for a wide range of bone regeneration materials (Hulsart-Billström *et al.*, 2016). This study evidenced a poor correlation between the in vitro observations and the in vivo regenerative outcomes. The great variability of used protocols certainly contributed to this discrepancy. Also, it evidenced the need in having a more complete assessment of the cell response, by focusing in other bone cell types and more representative models of the bone biology.

The Osteoclasts and Bone Resorption – In Vitro Models

Osteoclasts (1%–2% of bone cells) are motile multinucleated cells that resorb the bone matrix. They differentiate from hematopoietic myeloid lineage precursors, a process regulated by a variety of systemic and local factors, and complex intracellular signaling (Boyce *et al.*, 2012). Osteoclast precursors are present in the bone marrow and in the blood (here, as post-mitotic cells) being recruited to bone remodeling sites and subsequently differentiated into osteoclasts. Two cytokines are essential in osteoclastogenesis: macrophage colony-stimulating factor (*m*-CSF) and receptor activator of nuclear factor kappa-B ligand (RANKL).

Initially, M-CSF is needed for the proliferation and survival of osteoclast progenitors. Following, the expression of the receptor activator of nuclear factor kappa-B (RANK) characterizes the population committed to differentiate into osteoclasts. Upon the binding of this receptor to its ligand, RANKL, the precursor cells initiate a maturation process, involving the fusion of the mononuclear cells to form multinucleated and polarized cells, able to activate their resorptive mechanisms. RANK-RANKL binding

Fig. 1 Osteoblastic differentiation of human bone marrow-derived mesenchymal stromal cells (hBM-MSCs) cultured on a porous 3D bioceramic scaffold for 28 days: SEM images – (A) scaffold, (B) cell adhesion and spreading, (C) cell proliferation and pore migration, matrix formation, and (D) matrix mineralization inside the porous structure. triggers the activation of several signaling molecules, namely nuclear factor kappa beta (NF- κ B) and, finally, nuclear factor of activated T-cells 1 (NFATc1), the transcription factor critical for osteoclastogenesis; it translocate to the nucleus and promotes the expression of osteoclast-specific genes, such as tartrate-resistant acid phosphatase (TRAP), β 3 integrins, calcitonin receptors and cathepsin K (Teti, 2011). RANKL/RANK signaling also stimulates the capacity of osteoclasts to resorb bone and decreases osteoclasts apoptosis. Co-stimulatory mechanisms mediated by the osteoclast membrane immunoreceptors osteoclast-associated receptor (OSCAR) and triggering receptor expressed on myeloid cells 2 (TREM2) seem also to be important for osteoclastogenesis through the activation of NFATc1 (Boyce *et al.*, 2012).

Bone resorption involves the adhesion of multinucleated osteoclasts to the bone matrix, mainly through the binding of membrane receptors, especially β 3 integrins, to recognition sites on matrix proteins, leading to the formation of an actin-rich ring, defining and sealing the area to be resorbed. Inside the sealing zone, the re-organization of the cytoplasm allows the formation of a ruffled border membrane that greatly increases the surface area in contact with the matrix; additionally, polarized trafficking of endosomes and lysosomes to the ruffled border also occurs.

The resorption of the bone matrix is accomplished in two phases, i.e., dissolution of the mineral content, followed by the degradation of the organic components. The resorption lacuna is highly acidic which is attained by the combined actions of vacuolar ATPases and chloride channels in the ruffled border, that, respectively, pump protons and chloride ions into the lacuna. Hydrochloric acid is formed and dissolves the hydroxyapatite mineral phase, making the organic matrix available for proteolytic degradation by endosomal metalloproteinases and lysosomal proteinases (especially cathepsin K). Digested matrix proteins are taken up by endocytosis through the ruffled border, transported across the cytoplasm, and released by exocytosis into the extracellular space (transcytosis). Cytoplasmic vesicles, containing the specific enzyme TRAP, fuse with the transcytotic vesicles to destroy the endocytosed material. Osteoclasts have an average half-life of two weeks and die by apoptotic processes, regulated by paracrine mechanisms (Boyce *et al.*, 2012).

Osteoclastic cell cultures

Several osteoclastic lineage cells are used to establish appropriate cell culture models. They include cancerous/immortalized cell lines and animal- or human-derived osteoclastic precursors.

Precursor cells can be isolated from blood mononuclear cells (PBMCs), typically via density gradient centrifugation, by adhesion selection. The monocytes (osteoclast precursors) can be further isolated from PBMCs by using magnetic-activated cell sorting (positive CD14 and CD45 cells). Bone marrow consisting of supporting stroma and hematopoietic tissue may also provide osteoclast precursors present in the hematopoietic fraction. Additionally, two cell lines are frequently used. The human monocytic cell line THP-1 (derived from a boy with acute monocytic leukemia) and the murine leukemic monocyte macrophage cell line RAW264.7. In vitro, osteoclastogenesis is achieved by the exposure of precursor cells to M-CSF and RANKL (due to their roles in this process), added to serum-supplemented standardized culture media and a convenient culture time. RAW264.7 cells only

require RANKL exposure. Differentiation of human PBMCs is routinely used to assess the osteoclastogenesis and osteoclasts functional activity (Owen and Reilly, 2018; Costa-Rodrigues *et al.*, 2011).

For bioceramic testing, precursor cells are seeded on the material surface and cultured in appropriate conditions. Precursors adhere to the material through specific integrins and characterization of the elicited osteoclastic response takes into account the morphological features, differentiation of the precursor cells, and functionality of the mature osteoclasts. On the material surface, mature osteoclasts are easily identified by the presence of several nuclei and the typical circular F-actin cytoskeleton arrangement needed for the formation of the sealing zone. For the osteoclastic differentiation, markers commonly evaluated include the expression/secretion of integrin $\beta 3$ and integrin αv , RANK and calcitonin receptors, and the enzymes cathepsin K and TRAP. Functional activity is analyzed by the formation of resorption pits in the ceramic surface. For the underlying mechanisms, relevant signaling pathways' activation are assessed (Costa-Rodrigues *et al.*, 2016), Fig. 2.

The Bone Remodeling Cycle – In Vitro Models

Bone remodeling occurs in specific and specialized vascularized entities, the bone remodeling compartments, likely formed by an extension of the bone lining cells, which provide the structural basis for coupling and regulating the cellular activity. Remodeling requires a functional cohort of cells, the basic multicellular unit (BMU), which involves the coordinated action of bone cells, i.e., lining cells, osteocytes, osteoclasts and osteoblasts, and endothelial cells to support angiogenesis (Teti, 2011), Fig. 3. It comprises four major distinct but overlapping phases – activation, resorption, reversal, and formation.

Activation is the event that converts a defined resting surface into a remodeling site. The induction signal appears to be determined by the matrix through the osteocyte communication network (the bone sensing system), by detecting mechanical and biochemical stimuli (e.g., micro-damage, ischemic events). Transduction of these signals, via paracrine modulation, leads to the appropriate cellular activity at the bone surface (Bonewald, 2011).

As a result, osteoclast precursors are recruited from the surrounding marrow or the bloodstream, and differentiate into active osteoclasts. Bone lining cells that secrete M-CSF and RANKL, and the osteocytes – major producers of RANKL – have a role in this process. Osteoblast-lineage cells also secrete OPG, a key regulator of osteoclastogenesis. Osteoclasts attach to the bone matrix, resorb a portion of the underlying matrix and form a resorption lacuna – a process completed in few days. Osteoclast apoptosis is subsequently activated, liberating the remodeling area. Ending of this phase is related with several factors, i.e., increased local calcium and phosphate concentration (resulting from the degradation of the bone matrix), release of factors from the degraded matrix, signals from the osteocytes, among others (Boyce *et al.*, 2012).

The reversal phase, lasting 7–14 days, begins with the appearance of a heterogeneous population of macrophage-like mononuclear cells in the resorption lacunae. The lacuna is leveled by the removal of the matrix debris left behind during the

Fig. 3 Simplified view of the cellular and humoral interactions within the RANK/RANKL/OPG signaling in the bone remodeling compartment. OB: osteoblast; OC: osteoclast.

osteoclast activity, and a cement line enriched in proteoglycans, appears, demarcating the edge at which osteoclasts stopped their activity. This is a critical period between bone resorption and bone formation, with a role in the coupling of the two processes. Reversal cells may release relevant factors for the following bone formation phase, and/or might contribute to the formation of the cement line that may play a role in guiding osteoblasts during the bone formation phase (Teti, 2011).

Subsequently, osteoblast precursors are recruited to the resorption lacuna and differentiate into osteoblasts. A variety of factors with osteoblastic anabolic effect, released from the bone matrix during the resorption phase (e.g., TGF β , BMPs, PDGF, FGFs, IGFs), play a role in this process. Also, osteoclasts modulate osteoblastic cell behavior through several mechanisms, including the secretion of sphingosine 1-phosphate, the ephrinB2/EphB2/B4 and semaphorin/plexin signaling (Owen and Reilly, 2018). The functional osteoblasts lay down a collagenous organic matrix, the osteoid, that later becomes mineralized by the deposition of hydroxyapatite. This is a slow phase, taking three to four months, during which the more mature osteoblasts are entrapped in the organic matrix, becoming osteocytes. At the end of the formation phase, the resorption lacuna is completely filled with new bone, without any changes in the total bone amount. The mechanisms involved in the termination of this phase are unclear, but the major signal is very likely released by the osteocytes embedded in the mineralized matrix. Osteocytes secrete sclerostin that prevents the activation of the Wnt signaling, an important osteoblast inducer.

The strict control of bone remodeling is achieved by a complex bone-cell and humoral crosstalk. Extracellular vesicles (exosomes) play a key role in cellular crosstalk. The vesicles carry a variety of key molecules, i.e., BMPs, non-collagenous matrix proteins, RANKL and OPG, and an array of microRNAs that can modulate the differentiation and activity of bone cells (Yin *et al.*, 2017; Gao *et al.*, 2017). The role of circulating microRNAs must also be accounted (Yin *et al.*, 2017).

The adult skeleton has approximately 1–2 million active remodeling sites at any given time, replacing a volume of $\sim 0.025 \text{ mm}^3$, in each microsite. The lifespan of a single BMU is about 6–9 months, during which several generations of osteoclasts and osteoblasts are formed. The rate of remodeling of the skeleton, as a whole, is 5%–10% per year. Imbalance between resorption and formation compromises bone homeostasis, leading to bone metabolic disorders (Teti, 2011).

Co-culture models of osteoblastic and osteoclastic cells

In vitro models of bone remodeling require the communication between osteoblastic and osteoclastic cells (Goers *et al.*, 2014; Zhu *et al.*, 2018). Several protocols are used in co-culture models, to math distinct research purposes, however all within two

Fig. 4 (A) Representative co-culture models; (B), co-cultured human bone marrow-derived mesenchymal stromal cells (hBM-MSCs) and human peripheral blood mononuclear cells (hPBMCs) on the surface of a bulk hydroxyapatite substrate, for 21 days. approaches, i.e., the simultaneous cultivation of two (or more) cell populations allowing direct (via gap junctions) or indirect (via paracrine pathways) communication with each other (Roeder *et al.*, 2011), Fig. 4.

The direct methodologies imply the culture of both cell types on the same surface, with a defined/optimized cell-cell ratio (Costa-Rodrigues *et al.*, 2012). Here, both the effects of cell-to-cell contact and soluble factors are involved. However, conventional normalization methods for parameters such as mitochondrial activity, expression of genes and protein or DNA content, do not differentiate between the different cell types. Other approaches are used to visualize cell organization, quantify the number of cells and evaluate the differentiation of each cell type. Fluorogenic staining and phenotype immunofluorescence staining, and cell separation by cell sorting are useful tools in this scenario (Zhu *et al.*, 2018).

In the indirect co-culture models, one of the cell types is cultured on the material surface and exposed to the conditioned medium from the other cell type culture (performed in standard tissue culture plates or also on the material surface). Another approach requires a permeable membrane to separate the two cell types in the culture reservoir, but allowing the exchange of soluble factors. With this kind of set up it is possible to have the material samples cultured with distinct single cell types separated by the membrane, and to analyze the reciprocal paracrine interactions on each population (Zhu *et al.*, 2018). Using a transwell insert in the culture reservoir, the material surface may be seeded with one of the cell types, and the permeable membrane with the other cell type, also characterizing the behavior of each cell population.

The common osteoblastic and osteoclastic cell types used in the monoculture models, and referred previously, are commonly used to establish co-culture models. A great variability of combinations of the two cell types have been described (Owen and Reilly, 2018). In general, primary osteoblast-lineage cells and monocyte-derived osteoclasts are more representative models, especially, for long-term studies, because of the normal phenotype differentiation. Human mesenchymal stromal cells (hMSCs, normally from bone marrow) and peripheral blood monocytes (PBMCs) are recognized cell populations targeted to analyze the interactions of osteoblastic and osteoclastic cells. This system has the advantage of avoiding the use of phenotype-inducer supplements because of the reciprocal cell differentiation induction (Schulze *et al.*, 2018). As mentioned before, other primary cells, especially rodent cells, are also used to overcome the limitations of using human cells, namely regarding availability and donor variables (Czekanska *et al.*, 2012). Also, osteoblastic and osteoclastic cell lines are used to analyze the reciprocal phenotype interactions, being useful models to address particular targets (Zhu *et al.*, 2018; Owen and Reilly, 2018).

The reported culture media are highly variable in their formulation, due to the distinct requirements of the two cell types, the experimental approach and the research purpose (Baker, 2016; Owen and Reilly, 2018). Nevertheless, in a variety of studies,

osteogenic-induced conditions usually include supplementation with dexamethasone, β -glycerophosphate and ascorbic acid, while osteoclastogenic medium is typically supplemented with M-CSF and RANKL. However, these compounds are not always included or even needed, and other molecules may be added, such as Vitamin D, parathyroid hormone and retinoids (Owen and Reilly, 2018). The appropriate/optimized culture media formulation is determined by the osteoblastic- and the osteoclastic-lineage cells that are used (immortalized cell lines, cancerous cell lines or primary cells and their origin) and the research purpose (short- or long-term interactions, intended cell characterization). In the direct co-culture procedures, the compatibility of the cell types in culture, their seeding protocols (cell ratio, order, simultaneous or temporal spaced seeding) and particular supplements' needs, must be accounted for proper medium selection (Zhu *et al.*, 2018).

Characterization of the cellular behavior involves a panel of methodologies addressing several aspects related to cell adhesion and spreading, re-organization of the cytoskeleton during the initial cell-material interactions, rate and pattern of cell growth, phenotype differentiation markers and functional activity. The appropriate methodologies are conditioned by the co-culture set up, Fig. 4.

Multi-culture models

Bone remodeling requires proper blood supply and, thus, incorporating vascularization (in vitro, microvascular endothelial cells) appears interesting to mimic remodeling.

Tri-culture models involving osteoblasts, osteoclasts and endothelial cells have been established and results showed mutual phenotype interactions in terms of viability, proliferation and functional activity, compared to single- or two-cell type cultures (Pagani *et al.*, 2018; Grémare *et al.*, 2019). In the same line, a tetra-culture model was described involving endothelial cells, MSCs, MSCs differentiated into osteoblasts and osteoclast mononuclear precursors, showing that the presence of endothelial cells had a positive effect on the osteogenic and osteoclastogenic differentiation, with all the four cell types having synergic effects (Bongio *et al.*, 2016).

Immune Cells Involved in Bone Remodeling

The immune system and the bone tissue are closely related, sharing a variety of cytokines, receptors, signaling pathways and transcription factors (Chen *et al.*, 2016). The initial immune response elicited by the biomaterial, strongly depending on its physicochemical profile, is an essential player in the outcome of the material osteointegration/replacement and long-term performance. Abnormal immune response leads to an imbalance between osteoclastogenesis and osteogenesis, resulting in poor remodeling, normally favoring bone loss and implant failure. Characterization of the immune response elicited by the material should be included in a standard evaluation protocol (Chen *et al.*, 2016).

Complex immune cellular and humoral crosstalk modulates osteoclastogenesis and osteogenesis through three major cytokines associated to these events, M-CSF, RANKL and OPG. During normal bone remodeling, T and B-lymphocytes cooperate in the process of basal bone turnover to maintain bone homeostasis. RANKL is expressed by activated T-cells and neutrophils, and, in turn, B-lineage cells are the major source of bone marrow-derived OPG (Pacifci, 2010). A variety of immune mediators elicits indirect effects on osteoclastogenesis and osteogenesis, acting through the M-CSF/RANKL/OPG axis. IL-1, TNF- α , IL-6 and oncostatin promote, alone or in combination, osteoclast differentiation and function. Otherwise, TGF- β , IFN- γ , IL-17, BMP-2, and VEGF favor osteogenesis and bone formation.

Among the immune cells, macrophages have multiple roles in the bone healing. These cells are broadly classified into M1 and M2 phenotypes, based on their distinct biological profile. In a simple view, the pro-inflammatory M1 subtype (producing osteoclastogenic cytokines), appears to be dominant in the early stages of the repair process during the acute inflammatory reaction. The M2 subtype plays a more relevant role during the mid- to late stages of the process and, by releasing different cytokine patterns, might lead to either the formation of a fibrocapsule or the formation of new bone, at the bone-implant interface (Chen *et al.*, 2016). Conversely, bone cells also modulate immune cells. For instance, osteoclasts secrete TNF, IL-1 and IL-6, amplifying osteoclastogenesis and inflammation, and activated MSCs can induce the macrophage phenotype M2, decreasing inflammation and stimulating the healing process (Yiostalo *et al.*, 2012).

In vitro, biomaterials can be assessed in the presence of immune cells (e.g., neutrophils, mast cells, monocytes/macrophages), to analyze reciprocal interactions, applying the usual cell culture/material methodologies. Culture models using macrophages are a relevant tool due to the important role of this cell type in the bone repair process (Rayahin and Gemeinhart, 2017; Huang *et al.*, 2018). However, in a more integrated view, in vitro evaluation of the osteoimmunomodulation properties of bioceramics is more challenging. Proper models should incorporate the interactions between biomaterials, bone cells and immune cells, thereby involving indirect and direct co-culture systems (Chen *et al.*, 2016; Kohli *et al.*, 2018). In the simplest indirect co-culture protocols, the biomaterial is first cultured with immune cells and the attained conditioned medium is further used to feed osteoblastic and osteoclast cells to evaluate the effects on osteogenesis and osteoclastogenesis, respectively. A more representative model is the use of a transwell insert in the culture reservoir. Here, the immune cells can be cultured in indirect contact with the materials and the bone cells, allowing the simultaneous interaction of the three players, and to characterize separately the two cell types in culture. The co-culture of immune and bone cells on the biomaterial surface was also described, but this method appears to have poor reproducibility and the characterization of each cell populations implies troublesome methods of cell sorting.

In vivo Models for Bioceramics' Biological Characterization

A wide range of animal models has been commonly used in bone tissue-related research, as a platform to address and characterize the biological response of ceramic-based biomaterials, at the molecular, cellular and tissue level, further assisting on the characterization of the biocompatibility, osteoconductivity/osteoinductivity/osteoinductivity, mechanical functionality and degradation process of developed bioceramics. By assisting on the translation of in vitro outputs into clinical testing, experimental animal models allow a further understanding of the healing/regeneration process, establishing a controlled and standardized research setting for translational data validation. Herein, we approach and discuss the commonly used animal species and defect models for the characterization of bioceramics and related biomaterials for bone tissue application.

Animal Species

Established literature overview supports the use of distinct animal species in orthopedic-related research, including the rat (36%–38%), rabbit (13%–19%), mouse (15%–26%), sheep (11%), dog (9%), goat (4%), primates (3%) with the remaining including less used models as the pig, sheep and cat (O'Loughlin *et al.*, 2008; Martini *et al.*, 2001). From a biological point of view, no single model provides a fulfilled and representative comparison to the bone healing process of humans, with a wide variation in anatomical, biochemical and biomechanical characteristics of the bone tissue and related healing process, attained between species and individual strains (Aerssens *et al.*, 1998). As so, each model should be carefully selected in order to address adequately a particular research question, normally sustaining a progressive research approach, starting from small animals (as mice, rats and rabbits) into a higher phylogenetic complexity (as with dogs, goats, pigs, or sheep), in accordance with guidelines for market approval of ISO standards and regulatory agencies' policies.

The selection of a particular animal model is thus a determinant step in the study protocol establishment, and should entail the biochemical and microstructural characteristics of the bone tissue, as well as those of the healing process. Macrostructural differences, in gross anatomy and cortical/cancellous distribution should further be acknowledged, as they can influence the biomechanical parameters that greatly modulate the healing outcome. Age and endocrine status are further variables that can have a significant impact on the outcome of bone repair and regeneration, and thus are important to define and control (Muschler *et al.*, 2010). Other factors that should be taken into consideration throughout the study design regarding animal selection include animal size, cost for acquisition and maintenance, availability, ethical/social acceptability, easy of manipulation, staff familiarity and technical capacity, biomarkers availability, among others (Auer *et al.*, 2007; Pearce *et al.*, 2007). In addition, and according to regulatory standards, one should further consider the dimensions of the test biomaterials/constructs, number of implants per animal, duration of the biological evaluation and attained biological differences between species (Ghasemi-Mobarakeh *et al.*, 2019).

Rodent models

Rodents embrace a wide group of strains of both mice and rats, being characterized by significant dissimilarities of metabolic and structural characteristics of the skeleton, as comparing to humans. It is of mention the modeling-driven skeletal organization, the open growth plates at long bones' epiphysis, the absence of organized Harversian systems, predominance of cortical bone and limited cortical remodeling or secondary osteon formation (Pearce *et al.*, 2007; Erben, 1996). Notwithstanding, cancellous implant studies can still be conducted at the distal femur and proximal tibia locations, regardless of the established size limitations for multiple implant evaluation (Gomes and Fernandes, 2011). Nonetheless, multi implants can be placed on the calvarial bone considering sub-critical size defects and the predominant cortical organization of parietal bones (Gomes and Fernandes, 2011).

Rodents further present a high bone growth rate, established throughout the largest portion of life expectancy, thus continuing significantly after maturity, with the onset of puberty being disassociated from the process of growth plate closure contrariwise to other species (Kilborn *et al.*, 2002). Rodents also report an increased mineral density of the cancellous and cortical bone, as comparing to humans and other species – high levels at the trabecular structure might be related to the fewer but thicker *trabeculae*, while increased cortical density might be associated with the decreased intracortical remodeling, as comparing to higher species (Jerome and Peterson, 2001; Bagi *et al.*, 2011).

On the other hand, rodents, given their small size, low cost of either acquisition and maintenance, and easy manipulation, are broadly considered for first-line models for in vivo assessment of bone tissue regenerative strategies, given the well-established models, wide availability of biomarkers and comparative background data (Gomes and Fernandes, 2011). In addition, rodent species are well defined genetically, and can further be easily manipulated in order to address molecular approaches within the research purposes. In this context, immunocompromised mice and rats can be used for the biological assessment of tissue engineering constructs composed of allogenic and xenogenic constituents (McGovern *et al.*, 2018).

Rabbits

Rabbits are small mammals of the *Leporidae* family and *Lagomorpha* order, frequently used in bone-related research since they are easily available, are easy to house and manipulate and display a convenient size. Long bones, such as the tibia and femur, as well as the calvaria, are favorite locations for both cortical and cancellous implant studies – with the tibia being the most easily accessible and the femur allowing for adequate internal fixation (Burkholder *et al.*, 2012). Skeletal maturation – which is attained at the relative young age of 6 months – allows for the biocompatibility assessment in cancellous bone at the femoral condyles, and

also, contrariwise to rodents, at the calvarial location, with monocortical and bicortical defects being established and widely applied in research. Additionally, rabbits, as compared to rodents, present a more secondary osteonal remodeling, more similar to the process attained in the human bone (Muschler *et al.*, 2010), and are considered young adults at the time of epiphysis closure (Kilborn *et al.*, 2002).

Structurally, significant differences exist between rabbits' bones and those of human, regarding both shape and size, and as also in terms of biomechanical loading, given the distinct posture and movement of both species. Bone structure of rabbits' long bones relies on a primary longitudinal distribution of osteons, parallel with the long axis surrounding the medullary canal and periosteum. Rabbits also report a fast bone turnover, as comparing to other species, with a significant intracortical Haversian remodeling (Castañeda *et al.*, 2006) - which can be less representative of the human healing process. Rabbits, as rodents, present a higher cortical bone mineral density as comparing to higher models, possibly related to the reduced intracortical remodeling verified in these species (Bagi *et al.*, 2011), which further justifies a higher fracture resistance of the long bones, attaining values similar to that of humans (Wang *et al.*, 1998).

Dogs

Canine species are broadly used for the biocompatibility assessment of bone regenerative approaches, particularly within the dental and craniofacial field, considering the anatomical and tissue similarity, as well as the ability to develop periodontitis and peri-implantitis disease models similar to the human conditions (Albuquerque *et al.*, 2012; Berglundh *et al.*, 2003). Structurally, dogs and humans bones share numerous similarities including the formation of secondary osteons, cortical remodeling, as well as similar organic and inorganic composition. Haversian structure embraces 3–5 lamellar concentric rings, and relatively small Haversian canals in proportion to the osteon size (Morris, 2007).

Comparatively, a structure closely to that of the human bone is attained, with eventually a small dimension of the osteon diameter of dogs. Additionally, dogs' bone tissue is characterized by the existence of plexiform (laminar) bone in the close vicinity to the periosteum and endosteum – an histological type associated to rapidly growing animals and seldom observed in human children during large growth spurts (Cattaneo *et al.*, 2009). This tissue is structured more rapidly than secondary osteons, and characterized by a “brick wall” effect, elapsing from the radial, circumferential and longitudinal organization of primary osteons with rectangular vascular spaces, and rarely alternating lamellar bone layers (Hillier and Bell, 2007; Mulhern and Ubelaker, 2001). Additional differences are related with the higher trabecular turnover rates in dogs, averaging $2\text{--}5 \times$ times as compared to humans (Reichert *et al.*, 2009). Apposition and remodeling rates seem to vary significantly between bones of the same animal, as well as between breeds (Huja and Beck, 2008).

Pigs

Pigs have also been largely used within bone-related research given the established anatomical, morphological and biochemical similarities with the human bone. Notwithstanding, these animals may be difficult to manipulate, given their high end body weight and more aggressive behavior, being often disregarded in the favor of goats and sheep. Accordingly, miniature pigs and micropigs have been developed in order to prevail over these limitations, with significant success (Wang *et al.*, 2007; Ruehe *et al.*, 2009).

In pigs, tibias and femurs are proportionally small, considering animal weight and structure, which can preclude the assessment of multiple human-size implants; however, calvarial bone and the maxilla can be effectively considered for translational applications. Pigs' bones present a great similarity to human's bones regarding structure, mineral density and mineral concentration, remodeling – occurring both at trabecular and intra-cortical locations – and healing – with the regeneration rate being the most close to the one of humans (Reichert *et al.*, 2009). A lamellar bone microstructure, resembling those of humans, has also been described, despite the denser trabecular organization (Wancket, 2015). In immature animals, the presence of plexiform bone is also abundant within cortical locations of long bones (Hillier and Bell, 2007).

Sheep and goat

Sheep and goat are embraced as reliable models for the assessment of translational bone regenerative therapies, given the adequate dimensions of long bones and biomechanical loading, and similar body weight to humans (Martini *et al.*, 2001; Kruyt *et al.*, 2004). The macrostructure of the bone tissue is quite similar to that of humans in both sheep and goat, however, the tissue is essentially structured by primary bone with osteons presenting less than 100 μm , while humans present a broadly secondary bone organization (Jordana *et al.*, 2016). Further, both species present a non-uniformly distributed Haversian organization throughout individual bones, being these systems particularly concentrated at specific bone sectors (e.g., cranial portion of the tibial diaphysis) (Dias *et al.*, 2018).

Sheep, up to 3–4 years of age, present a predominant plexiform bone structure, with secondary remodeling not occurring prior to the 7–9 years of age (Li *et al.*, 2015). Mature animals present a high trabecular bone density, superior to that of humans up to 2 times, further associated with an increased bone strength and higher bone ingrowth rate (Willie *et al.*, 2004). Notwithstanding, significant differences seem to be associated with the anatomical location (Liebschner, 2004). Immature animals, on the other hand, are characterized by a low-density trabecular structure that is broadly flexible given the increased collagenous content (Nafei *et al.*, 2000). Goats broadly report a metabolic rate and remodeling rate at the bone tissue, similar to that of humans (Pearce *et al.*, 2007), with a sequence of bone ingrowth similar to the one described for sheep (Pearce *et al.*, 2007).

The experimental manipulation of ruminants implies specific considerations regarding handling and housing, given their size, as well as through the perioperative period, namely throughout anesthesia and ventral recumbence position (Dias *et al.*, 2018).

Non-human primates (NHPs)

NHPs are widely characterized and used models within bone tissue applications, given the high genetic homology with humans and similarity on gait, posture, skeleton and bone tissue structure, organization and osteonal remodeling (Jerome and Peterson, 2001). Used species include African green monkeys, (*Cercopithecus aethiops*), Rhesus macaque (*Macaca mulatta*), and baboon (*Papio hamadryas*) as well as marmosets. NHPs are particularly relevant models within bone implant research in which the biomechanical component is not adequately mimicked by other species – anatomical locations such as the femur, ileum, vertebral bodies, ribs' cortex, mandible and calvarial are commonly considered. However, long bones-related assessment are broadly appropriately matched for distinct large models, as those from NHPs may be too small to support human translational implants, given the inferior total body weight and proportional bone size of the most commonly used species, only baboons approach the humans' skeletal size range (Muschler *et al.*, 2010). Furthermore, it has been presumed that NHPs' models allow for the most extrapolative and clinical predictable research for the assessment of immunological and biological response, given the similarity in the biological milieu, anatomy, endocrine and major systems' functionality. However, attained response outputs seem to be as heterogeneous, or even more, than those attained with quadrupeds' models, substantially diminishing this argument (Muschler *et al.*, 2010). NHPs-based research is also significantly expensive due to the price of animal acquisition and critical-care maintenance. Furthermore, substantial social and ethical issues should be largely acknowledged on the experimental use of these animals.

Models of Ectopic Bone Formation

Prior to the characterization of bioceramics within an orthotopic bone model, a first-stage evaluation is generally conducted within an ectopic model. Ectopic derives from the greek word *ektos* (away from a place), and refers to the process of ossification/mineralization in an anatomical location distinct from its usual origin – i.e., the bone tissue. Ectopic bone formation is normally evaluated in small animal models (rodents and rabbits) and allows the evaluation of the biological response in the absence of bone-specific growth factors, and endogenous local or recruited bone forming cells and related precursors, sustaining a particularly controlled milieu for the evaluation of the in vivo experimental bone formation (Scott *et al.*, 2011). It is further assayed in the absence of biomechanical stimulation – eventually some compressive forces may be established, depending on the construct/implant size, and particularly on the kidney capsule model – thus minimizing bone-stimulating mechanotransduction (Scott *et al.*, 2011). Data analysis may also be hindered by the eventual resorption of the newly formed ectopic bone (Eyckmans and Luyten, 2006).

Ectopic assessment is of particular relevance for the characterization of osteoinductive structures, or tissue engineering constructs containing bone-forming cells or related growth factors. Different anatomical locations have been used with success, including intramuscular, subcutaneous, and kidney capsule locations.

Ectopic models are relatively economic and cost-effective, yielding fast and potentially translational results that allow for the research progression into more clinically relevant approaches (Eyckmans and Luyten, 2006; Scott *et al.*, 2011). Usually, constructs or biomaterials are implanted in the defined anatomical region and, after an appropriate period of time, are excised with the neighboring tissue and examined through imagiological and histological techniques to address the existence and characteristics of newly formed bone tissue (Scott *et al.*, 2011). Diffusion chambers may be used to assay fast releasing substances. While small animals are generally preferred, established differences on the attained biological response exist between species (Westhauser *et al.*, 2017; Eyckmans and Luyten, 2006).

Subcutaneous implantation

The implantation in subcutaneous tissue is the simplest experimental procedure for ectopic evaluation that can be established in any common animal model. Rodents are generally preferred for economic reasons, as well as the lax skin that facilitates the accommodation of large volume implants and availability of genetic-manipulated and immunodeficient models that allow heterogenic and xenogenic assessment.

Incisions are normally conducted on the dorsum, minimizing the risk for the animal to remove the stiches and sutures (Hoogstraten-Miller and Brown, 2008). Care should be taken regarding the physical identification of the implant/biomaterial, as throughout the healing period, grown tissues mimic the surrounding subdermal tissues. The lax skin of rodents also allows for implant/biomaterial migration, which can difficult its recover upon the end of the implantation period.

Subcutaneous location is also characterized by the general absence of bone-forming precursor or mature cells – as in comparison to the intramuscular location in which resident precursor cells might differentiate into the osteogenic lineage upon adequate stimulation – which can be an advantage or a hindrance, depending on the experimental protocol and study objectives. Additionally, a reduced blood flow and vascularization is attained in subcutaneous locations, as comparing to intramuscular, or the kidney capsule model. As so, a decreased bone formation is normally attained in the subcutaneous model, as comparing to other target model locations (Habibovic and de Groot, 2007; Yang *et al.*, 1996).

Intramuscular implantation (muscle pouch)

Intramuscular implantation, as the subcutaneous location, can be largely applied to a vast range of animal models, despite the preference for the use of rodents (Asatrian *et al.*, 2014). In these animals the hind limb is a preferred location, allowing for the use of larger implants, while the lower leg, on the other hand, entails the use of smaller implants but facilitates palpation and surface identification (Scott *et al.*, 2011). In large animals, the dorsal musculature is generally preferred (Willie *et al.*, 2004).

Intramuscular implantation is associated with an increased bone formation process, given the verified activation of BMP-signaling cascade and other osteogenic-signaling pathways upon the established muscle injury, for implant/biomaterial placement (Asatrian *et al.*, 2014). One must further considered the recruitment/activation of muscle-related precursor cell populations (e.g., satellite cells) that can, upon adequate stimulation, induce the local osteogenic process. An atraumatic surgical procedure, embracing a blunt-dissection approach is thus required to minimize tissue activation.

Kidney capsule implantation

The kidney capsule implantation model, due to its technical/surgical difficulty, is less used than prior ectopic models. Implant/biomaterials are to be placed between the renal parenchyma and the capsule of the kidney, either by injection or following incision – given the creation of adequate space by blunt dissection. Care should be given to keep the capsule intact ensuring adequate implant confinement (Cunha and Baskin, 2016).

Renal capsule implantation is associated with supra-physiological blood flow and nutrient supply to the implant, which may significantly increase the bone formation response, as comparing to other ectopic models (Scott *et al.*, 2011). Implant size must be critically selected to prevent capsule damage and is generally inferior to that used in intramuscular and subcutaneous approaches. Also regarding size, large-volume implants can induce compressive forces which may influence the biological outcome (Scott *et al.*, 2011).

Models of Orthotopic Bone Formation

Orthotopic models are broadly used for the assessment of the efficacy and biosafety of new biomaterials/tissue engineering products or bone regenerative procedures, with investigational procedures being established in or around the bone tissue. Orthotopic derives from the greek work *orthos*, that refers to “right, straight” defining an approach on the correct anatomical location, in this case, the bone tissue. Different approaches can be employed within this context, being either non-surgical (e.g., injection of materials into long bones’ periosteum) or surgical (e.g., a calvarial drilled defect or long bone segmental defect, with materials grafted on the defect site) (McGovern *et al.*, 2018). The most commonly approaches include the calvarial/mandibular defect, the long bone segmental defect, partial cortical defect and cancellous bone defect, with the former two being the most widely used and following addressed (Bigham-Sadeh and Oryan, 2015).

Calvarial/mandibular bone defects

The calvaria bone defect is commonly conducted in small animals (i.e., rodents and rabbits) (Gomes and Fernandes, 2011) despite its successful application in larger animal models (Szpalski *et al.*, 2010). The calvarial defect is a well-established and adequate model given the macrostructure of the calvarial bone, allowing the establishment of uniform and standardized defects that can be easily characterized through imagiological or histological techniques, with minor influence of neighboring structures. Further, the calvarial approach allows for an adequate surgical access and biomaterial/construct implantation in different animal models, given the support provided by the dura mater and associated tissues. However, this defect model does not allow for the bone healing process under physiological mechanical loading, which might be of relevance for particular applications (Gomes and Fernandes, 2011). Overall, it is a widely used model, so vast amount of background data is available, which thus facilitates data analysis and comparison (Spicer *et al.*, 2012).

Briefly, a full-thickness anteroposterior mid-sagittal incision is created and a flap is subsequently raised and retracted to expose the calvarial bone. A standardize circular defect is following established, usually with a trephine burr under copious irrigation, involving the complete thickness of the bone – normally the parietal. Care must be given to prevent dura damage by periodically checking osteotomy depth, for which a neural or periosteal elevator can be used. The drilled bone disk is then carefully elevated and biomaterials/constructs are implanted in the volume of the created defect. Following, the periosteum is repositioned and sutured, and the overlying muscular tissue and skin flap are positioned and sutured, Fig. 5.

When establishing a surgical bone defect, the overall dimensions of the defect is a critical point that needs to be copiously considered. Critical size defects (CSDs) have been classically defined as those intra-osseous located, that present the smallest size, for a given bone and species, that are not able to heal spontaneously throughout the lifetime of the animal (Schmitz and Hollinger, 1986). These were developed to model human nonunions, establishing defects that were unable to heal on their own. Subsequently, the definition was revised to the defects in which the bone regeneration was inferior to 10%, throughout animals lifetime (Hollinger and Kleinschmidt, 1990). Despite widely disseminated, these concepts seem to lack functionality, given the majority of studies are of limited duration and do not extend over the animals’ lifetime (Cooper *et al.*, 2010). As so, a more functional approach on CSDs definition relies on an established defect that does not heal over the duration of the study, leaving behind the idea of “smallest size bone defect” and concept of “lifetime of the animal” (Gosain *et al.*, 2000).

Even in this context, there is a wide range of dimensional variation of the CSD according to each species, further considering a wide variation according to the weight, age and strain, of a given species (Schmitz *et al.*, 1990). Circular defects, established with

Fig. 5 Regeneration of rabbit calvaria defects. (A), radiographic image of a 5 mm calvaria defect implanted with a bioceramic scaffold for 3 months; (B), microtomographic 3D reconstruction of a 5 mm calvaria defect implanted with a bioceramic scaffold (orange) for 3 months. Note the newly formed bone tissue at the defect volume (yellow); (C), histological section of a 5 mm calvaria defect implanted with a bioceramic scaffold for 3 months. Note the close interaction of the newly formed bone tissue (NB) with the biomaterial and the progressive resorption of the implanted scaffold. Scale bar of A and B correspond to 2.5 mm.

trephine burrs, have been widely conducted, given the consistency and easiness of the surgical procedure. Still, other defect configurations, ranging from oval, square, rectangular and trapezoidal have further been reported, broadly by the use of reciprocating saw or round dental burs (Mardas *et al.*, 2014).

In the mouse model, 3, 4, and 5 mm in diameter parietal defects were found to be critical sized in the adult, whereas significant healing was seen regardless of the size of the defect, in juvenile mice (Aalami *et al.*, 2004), leading to the overall acknowledgment that defects larger than 5 mm in diameter are critical size in nature for this species (Ning *et al.*, 2017).

In the rat, there has been controversy on the established CSD dimensions. Broadly, 5 mm in diameter are most commonly used, and were shown, after 12 months of healing, to allow for a minimal bone formation at the defect margin (Bosch *et al.*, 1998). The 5 mm defect allows the establishment of 2 defects per animal allowing a paired split design experiment, and the avoidance of the sagittal suture within the defect limits, which can alter the healing process (Gomes and Fernandes, 2011). On the other hand, some reports shown an increased healing at the defect margin with 5 mm defects, further advocating the use of 8 mm for CSDs (Hollinger and Kleinschmidt, 1990; Gomes and Fernandes, 2011).

In the rabbit, calvaria defects are generally located in the parietal, frontal or both bones, and the vast majority of studies employs a 15 mm diameter circular defect (Delgado-Ruiz *et al.*, 2018). Interestingly, the defect dimensions seems to have a direct influence on

Fig. 6 Regeneration of rat mandibular defects. (A) Intraoperative image of the establishment of a critical size defect (CSD) at the rat mandible (5 mm in diameter); (B) radiographic image of a 5 mm calvaria CSD defect, healed for 3 months; (C) microtomographic 3D reconstruction of a 5 mm mandibular CSD defect, implanted with bioceramic nanoparticles for 3 months. Note the newly formed bone tissue at the defect volume (pink), interspersed with particles remnants; (D) histological section of a 5 mm mandibular CSD defect, implanted with bioceramic nanoparticles for 3 months. Note the newly formed bone tissue with a cancellous organization. Scale bar of A, B, and C correspond to 2.5 mm.

the regenerative outcome, with defects larger than 15 mm sustaining an increased healing with longer regenerative periods (Delgado-Ruiz *et al.*, 2015, 2018). Defect smaller than 15 mm can also be considered CSDs, depending on the time of assessment (Delgado-Ruiz *et al.*, 2015). A similar size range has been established as CSDs in pigs and minipigs calvarial bone. Calvarial CSDs have been further established for other species, particularly the dog (20 mm diameter defects (Cui *et al.*, 2007)), sheep (22 mm diameter defects (Viljanen *et al.*, 1997)) and some NHPs, such as monkeys (15 mm diameter defects) (Brierly *et al.*, 2016).

In addition to the calvaria, the mandible can be also used for the establishment of circular full thickness (through-and-through) defects, offering an increased content of cancellous bone between the cortical structures. Furthermore, mandible offers the possibility to establish physiological biomechanical loading throughout the healing process, further mimicking a translation application, particular to dental and craniofacial-related applications, Fig. 6.

Whether rodents and rabbits have narrow and small mandibles, continuous (circular) defects are most commonly employed than segmental defects that further require adequate stabilization. CSDs for rat mandible have been established to be of 5 mm in diameter (Arosarena and Collins, 2003), a dimension similar to those established for rabbits (He *et al.*, 2008). In minipigs, at the lower border of the mandible, full-thickness 8 mm full thickness defects were established as critical size (Mardas *et al.*, 2014). Larger animal models report CSDs of increased dimensions – for instance in the dog, 20 mm defects have been established to be critical size (Cui *et al.*, 2007), while in sheep, 22 mm diameter defects are acknowledged to be CSDs (Brierly *et al.*, 2016).

Segmental bone defects

Long-bone segmental defects have been established, in distinct animal models, embracing the removal of a defined segment from a determined site of the bone. Globally, the established defect should allow the biomaterial/construct to be characterized under similar conditions to that required for clinical application (Gugala *et al.*, 2007). As for the calvarial/mandibular defect, and in order to create and reinforce the bone healing ability of nonunions, the segmental defect must be of enough dimensions to preclude the direct bone healing – bridging of the defect – that is, a critical size defect (CSD). As a rule of thumb, the defect should be 2–2.5 times the diameter of the long bone's shaft (Gugala *et al.*, 2007). Furthermore, other factors should be taken into the consideration for segmental CSDs' establishment, including the definition of species, age, anatomical location, presence of periosteum, biomechanical loading, endocrine and systemic condition, and as significantly different from calvarial/mandibular circular defects, the fixation process for the defect stabilization.

Distinct anatomical locations (e.g., tibia, femur, radius, ulna and humerus) have been considered, which further difficult comparative analysis of the data, given the established healing differences on the bone tissue itself, or supporting tissues, as the periosteum (Fuji *et al.*, 2006). Fundamentally, segmental defects can be established through osteotomy or trauma. Osteotomy endorses the use of a drill/burr or saw to remove surgically the defined section of the bone, from a predetermined location, establishing a high consistency between replicates (Reichert *et al.*, 2009). Alternatively, and in order to more closely mimic trauma-related clinical scenario, the defect can be created with a 3-point bending device, commonly employed for experimental fracture establishment, creating a sharp cut edge, injuring both the bone and involving soft tissues. This approach originates a larger variability on the established defects (Li *et al.*, 2015).

Ideally, a segmental bone defect should mimic clinical translational conditions, allow for adequate defect fixation, permit early biomechanical loading and facilitate the biological processes of healing (Horner *et al.*, 2010).

Within the mice, representatively, femoral mid-diaphysis 3.5–4 mm defects sustain the absence of bridging, with endochondral ossification at the defect margins and intramembranous ossification at mid-portion following biomaterials/constructs implantation (Tiyapatanaputi *et al.*, 2004; Manassero *et al.*, 2016). Alternative models have been created with reduced defect dimensions (e.g., 1.8 mm) but increased periosteum stripping, further highlighting the relevance of the periosteum on assisting bone healing (Garcia *et al.*, 2008). Radial defects (CSD – 4 mm) have also been largely used due to the attained high stability achieved by the ulnar support (Ning *et al.*, 2017).

In the rat, segmental CSDs of the tibia have been established within the 4–5 mm range, and between 5 and 10 mm within the femur (Garcia *et al.*, 2013). In the mandible, 5 × 5 mm full-thickness defects were found to correspond to CSDs (Arosarena and Collins, 2003). In the rabbit, CSDs of long bone have been found to range from 10 to 20 mm, in different long bone such as the humerus, radius, ulna, tibia and femur and mandible (Lu and Rabie, 2003; Zhao *et al.*, 2016; Crigel and Balligand, 2002) and significantly larger (50 mm), at the ribs (Liu *et al.*, 2016). For dogs, commonly used CSDs range from 20 to 70 mm in the femur (Jewell *et al.*, 2015), between 20 and 25 mm in the radius and ulna, and between 35 and 50 mm within the mandible (Marei *et al.*, 2018). In minipigs, critical size mandibular segmental defects have been determined as 60 mm and 20 mm, with and without periosteum stripping, respectively (Ma *et al.*, 2009), whether long bones CSDs seem to range within 25–30 mm. In sheep, used models rely on femoral CSDs ranging from 25 to 50 mm, tibial CSDs ranging from 20 to 50 mm, with the 30 mm defect being the most used (Jewell *et al.*, 2015; Lammens *et al.*, 2017).

The process of fixation is another fundamental aspect regarding the selection of segmental bone defects. It is expected that experimental fixation within animal models mimics the clinical scenario, allowing for sufficient defect stabilization that endorses bone healing (Reichert *et al.*, 2009). This is of additional relevance for load-bearing defects, as comparing to those established in naturally supported bones such as the radius or fibula. Internal fixation devices, such as intramedullary rods, screws and bone plates, or external devices as external fixators or cast and splints, are commonly used. Still, the vast majority of approaches are not originally designed for the application in experimental animal models, and its possible effect on the modulation of the healing process is largely unknown.

Conclusion

In vitro and in vivo evaluation of bioceramics is needed throughout the all process of material development, although with distinct meanings, aiming to end up with a safe and effective product for bone regeneration. In vitro assays, targeted for the evaluation of a bone regenerative material, inform on the bone cells' differentiation and functional activity at the bone cells/material interface. Further, downstream mechanisms underlying the elicited response might be analyzed in controlled and defined cell culture/material conditions needed to unveil molecular signaling pathways. However, the structural, metabolic and functional complexity of the bone tissue calls for appropriate in vivo experimentation to assess the bone regenerative efficacy of the biomaterial together with its local and systemic safety. In this way, the in vitro testing is expected to function as a reliable pre-screening to guide subsequent studies through the biomaterial testing pipeline.

The wide variability of the in vitro methodologies related with the cell type and passage, culture protocols, evaluated parameters and inferred results significance can result in significant data discrepancy, compromising its usefulness for predicting in vivo outcomes and, therefore, to guide on the further appropriate animal testing. Similar reasoning is applied to the in vivo testing, namely the results translation from the small animals to the large animal models and from the preclinical studies into clinical trials. Nevertheless, as a whole, in vitro and in vivo testing should provide reliable information for rapid and safe translation to the clinical setting. The predictability of these assays is continuously being improved due to the constant development of testing methodologies, together with standardization and validation strategies.

Background

Fixed partial dentures (FPDs) produced from modern dental materials are used in dental medicine to restore anatomic form and function, and/or esthetics. Traditional metal-ceramic restorations have had acceptable success rates, but are limited by pertinent concerns such as tissue compatibility and esthetics. Successful emergence of 3 mol% yttria partially-stabilized tetragonal zirconia (3Y-TZP) bioceramics in orthopedics gained an immense interest in dentistry in the early 90s. Owing to 3Y-TZP's high esthetics, chemical inertness, exceptionally high strength and toughness for a ceramic material, it advocated the replacement of traditional porcelain veneered metal-ceramic FPDs. It followed that in the past three decades, there have been profound advances in the application of 3Y-TZP in restorative dentistry further expanding clinical indications of tooth-colored, all-ceramic systems to crowns and bridges, root posts and even implants (Piconi and Maccauro, 1999; Denry and Kelly, 2008).

3Y-TZP ceramics exhibit high flexural strength (900 – 1200 MPa), fracture toughness ($4 - 6 \text{ M Pam}^{-1}$), and a lower Young's modulus (210 GPa) compared to alumina (340 GPa) (Piconi and Maccauro, 1999). Therefore, it is suitable to serve as a core material and withstand high stresses produced in the posterior dentition, where masticatory forces are higher due to the masticatory muscle attachment.

3Y-TZP's high strength and fracture toughness are governed by the stress-induced tetragonal-to-monoclinic (*t-m*) transformation toughening mechanism, where under applied stress the metastable tetragonal phase (grains) transforms to monoclinic. This causes volumetric expansion and creates compressive stresses that oppose the tensile stress in the vicinity of a propagating crack tip (Fig. 1(a)) (Butler, 1985). Because of this toughening mechanism, the 3Y-TZP ceramic was labeled as “ceramic steel” (Garvie *et al.*, 1975; Gupta *et al.*, 1978). 3Y-TZP's mechanical properties are far superior to other dental (glass) ceramics, such as feldspathic porcelain, lithium disilicate, alumina, allowing it to be also used in high load-bearing areas.

Pure zirconia (ZrO_2), an oxide ceramic polymorphic system, exhibits three different crystal lattice types under atmospheric pressure. At temperatures higher than 2370°C , zirconia occupies cubic lattice. Between 1170°C and 2370°C , zirconia is tetragonal, and below 1170°C the lattice is monoclinic. Upon cooling, the *t-m* phase transition is accompanied by 3 – 5 vol% increase, which facilitates cracking of the sintered bulk. The spontaneous phase transformation can be avoided by modifying the composition with traces of other oxides, such as MgO, CaO and CeO_2 . Such doping strategy results in partial stabilization of the tetragonal phase at room temperature, and thus cracking upon cooling is prevented and the stress-induced transformation toughening installed (Hannink *et al.*, 2004). Generally, biomedical grade zirconia used in dentistry is doped with 3 mol% of yttria (Y_2O_3) and a small amount of alumina (0.25 wt%). Such 3Y-TZP ceramics are characterized by fine-grained microstructures (0.3–0.5 μm) (Fig. 1(b)), where inclusions of distinct alumina grains can be found in the matrix (Samodurova *et al.*, 2015b).

Fig. 1 (a) Schematics of stress-induced *t-m* transformation toughening around an advancing crack, where transforming tetragonal particles to monoclinic symmetry form a process zone exerting compressive strain. (b) SEM micrograph of polished and thermally etched surface of the 3Y-TZP sintered for 2 h at 1450°C . Darker faceted grains are alumina inclusions. Reproduced from (a) Butler, E.P., 1985. Transformation-toughened zirconia ceramics. *Mater. Sci. Technol.* 1, 417–432. doi:10.1179/mst.1985.1.6.417, Copyright Taylor & Francis. (c) Chevalier, J., 2006. What future for zirconia as a biomaterial *Biomaterials* 27, 535–543. doi:https://doi.org/10.1016/j.biomaterials.2005.07.034, Copyright Elsevier.

3Y-TZP is pressure-less sintered at relatively low sintering temperatures (1350 – 1500°C) to produce full density ($\geq 99.5\%$). The addition of Y^{3+} replaces Zr^{4+} in the crystal lattice creating oxygen vacancies that maintain the tetragonal phase partially stable at room temperature after sintering (Chevalier *et al.*, 2009). A small amount of alumina is added to 3Y-TZP to prevent yttria segregation, which results in improved ageing resistance and reinforces grain boundaries (Matsui *et al.*, 2006; Samodurova *et al.*, 2015a).

However, the long-term stability of the 3Y-TZP ceramics is known to be susceptible to a superficial ageing phenomenon the so-called low-temperature degradation (LTD); a spontaneous *t-m* transformation of 3Y-TZP's surface in an aqueous environment at moderate temperature, including body temperature. At the onset of the present millennium, several hundreds of 3Y-TZP femoral heads failed in a short period following implantation, with the origin of the fracture indirectly associated with LTD (Haraguchi *et al.*, 2001). Since then, numerous studies have been performed to investigate the mechanisms and kinetics of LTD.

It was found out that the *t-m* transformation is temperature-dependent and diffusion-controlled, accompanied by extensive microcracking, and surface uplifting, which ultimately leads to strength degradation (Fig. 1(c)) (Chevalier, 2006). The LTD process was found out to be a grain-size dependent stress-corrosion-type mechanism starting at the 3Y-TZP's surface and proceeding into the bulk (Kosmač *et al.*, 2012; Hallmann *et al.*, 2012). It is sensitive to the differences in the starting materials and process additives (co-dopants) (Samodurova *et al.*, 2015a; Zhang *et al.*, 2016a; Bučevac *et al.*, 2017) and the materials' processing-related prehistory (grinding or sandblasting; Kosmač *et al.*, 1999; Chintapalli *et al.*, 2013; Cotič *et al.*, 2016). Moreover, some studies showed how the highly distorted tetragonal zirconia grains and pre-existing monoclinic zirconia in the ground and air-particle abraded surfaces hindered the *t-m* transformation during ageing (Kosmač *et al.*, 2008).

Déville and Chevalier established a relationship between the amount of the transformed monoclinic phase and the accelerated hydrothermal ageing time in an autoclave at 134°C in distilled water to estimate the equivalent ageing time under "in vivo" conditions based on the results obtained with retrieved 3Y-TZP femoral heads (Chevalier *et al.*, 2007; Chevalier and Gremillard, 2009). A postulation was made that one hour of ageing in vitro corresponds to about three years "in vivo". However, as stated above, 3Y-TZP ceramics may differ substantially in their fabrication method and properties, as well as in clinical conditions and it was later shown by Keuper *et al.* (2014) that such approximation of the ageing process to room temperature can result in important underestimation. However, at the moment, there are no obvious clinical indications that the LTD of 3Y-TZP used in dentistry would represent a severe concern.

In the beginning, the 3Y-TZP frameworks were produced by costly and time-consuming precise hard-milling of densely sintered and hot isostatically pressed 3Y-TZP blocks. Later, direct oversize milling of pre-sintered 3Y-TZP blanks has become increasingly popular in dentistry and is now the most common method in the fabrication of 3Y-TZP FPDs (Raigrodski, 2005). In this manufacturing technology, the die or a wax pattern is scanned, and/or enlarged restoration is digitally designed by computer software (CAD), and a pre-sintered ceramic blank is oversize-milled by computer-aided machining (CAM). The restoration is then sintered to full density. However, the process of milling of preformed zirconia blocks generates a lot of waste material that is environmentally unfriendly; therefore, new methods of zirconia fabrication have evolved recently.

Biomedical Grade Zirconia in Fixed and Removable Prosthodontics

Biomedical grade 3Y-TZP was initially used for the fabrication of orthodontic brackets (Keith *et al.*, 1994), root canal posts (Meyenberg *et al.*, 1995) and implant abutments (Glauser *et al.*, 2004). Afterwards, 3Y-TZP emerged as a strong and tough core material in all-ceramic FPDs. Nowadays, 3Y-TZP ceramics is a material of choice for the entire spectrum of fixed restorations, including inlays, onlays, single crowns, multi-unit bridges, and implant-supported restorations (Guess *et al.*, 2012). It may also successfully serve as an alternative option to implants and/or bridges of replacing missing lateral incisors in adolescents and young adults with a cantilevered resin-bonded fixed dental prosthesis (RBFDP) and thereby avoiding more aggressive treatment (Fig. 2).

In addition, several indications in removable prosthodontics exist, where 3Y-TZP ceramics is successfully implemented. There is a strong clinical evidence of double crown system, where primary crowns are milled from 3Y-TZP ceramics and secondary crowns galvano-formed in gold (Fig. 3(a)). This clinical protocol has been introduced by Weigl and Lauer (2000). The retention mechanism of the 3Y-TZP-galvano system is based primarily on the very precise manufacturing of both crowns. The template for the galvano-forming of the secondary crown is the primary ceramic crown itself. Consequently, a gap not exceeding 5 μm can be achieved. Retention of the system is therefore primarily based on capillary pressure and adhesion between the crowns. This way predictable and long-term stable clinical success can be achieved. Retention of the system also depends on the conical crowns' surface area and surface roughness of the materials. The proposed protocol includes intraoral bonding of the secondary galvano-crowns to the tertiary metal framework. This concept has also been extended to tooth-implant prosthetic rehabilitations (Fig. 3(a)), where custom made zirconia implant abutments serve as primary crowns (Brandt *et al.*, 2019).

Bar retained implant dentures are often designed in edentulous patients with head and neck cancer. This way, good denture retention and stability can be achieved. In the past, bars were cast from Co-Cr alloys. Currently they are milled from metal blocks in a CAD-CAM process. As there is a common trend to minimize metals in the oral cavity 3Y-TZP milled bars are indicated (Fig. 3(b)).

Bonding to Dental Zirconia Ceramics

The evolution of new generations of dental adhesives that promote a reliable bond between two chemically diverse materials, i.e., dentin or enamel and composite resin has enabled to replace conventional, retentive-based cementation techniques with adhesive

Fig. 2 A clinical case replacing lateral incisors resin-bonded fixed dental prosthesis (RBFDP): (a) before the prosthetic rehabilitation, (b) veneered zirconia dental prosthesis and (c) after the prosthetic rehabilitation.

Fig. 3 3Y-TZP ceramics applied in removable prosthodontics: (a) Primary telescopic crowns on abutment teeth and implants (lower left). bonding procedures of FPDs. To achieve a durable bond between 3Y-TZP ceramics and bonding agent, several methods have been proposed. Numerous “in vitro” and “in vivo” studies have been conducted to resolve the durability and strength of the resin bond (Kern, 2015), since chemical methods such as acid-etching and silanization, that are successful in luting of silicate ceramics, proved to be ineffective to promote adhesion of composite luting agents to zirconia surface due to the high chemical inertness and the absence of siliceous phases in polycrystalline zirconia matrix. It followed the advent of employing surface roughening of zirconia by air-particle abrasion (APA) with alumina particles also called sandblasting (Fig. 4(a)), which enhances the mechanical interlocking, which is the most commonly used surface treatment (Shahin and Kern, 2010). APA parameters, such as alumina particles size (30–250 μm), blasting pressure (0.05 – 0.6 MPa) and blasting distance, have been studied immensely. The interchange of these parameters has led to a consensus that APA with 50–110 μm alumina particles at 0.25 MPa is effective in cleaning and roughening zirconia ceramics as it most likely removes contaminants from ceramic surface and exposes a fresh bonding surface. The APA could theoretically lead to mechanical degradation of zirconia ceramics by producing microcracks and subsurface damage. Many authors have questioned the use of aggressive treatments of zirconia; however, several studies on the other hand demonstrated that APA improved the mechanical strength of 3Y-TZP presumably via transformation toughening mechanism irrespective of the blasting pressure (Kosmac *et al.*, 1999; Aurélio *et al.*, 2016; Chintapalli *et al.*, 2014; Cotič *et al.*, 2017).

It is fundamental to combine APA with the use of chemical promoters, capable of improving adhesion. Primers contain organophosphate monomers, including 10-MDP (10-Methacryloyloxydecyl Dihydrogen Phosphate), present a terminal functional group with phosphoric acid, which reacts with zirconia and forms P-O-Zr bonds. The other end of the molecule exposes a vinyl

Fig. 4 SEM micrographs showing (a) APA modified 3Y-TZP surface; and nanostructured alumina coating deposited on the as-sintered 3Y-TZP surface: (b) coatings' topography; (c) cross-sectional view (1 – coating; 2–3Y-TZP substrate). Reproduced from (b, c) Malgaj, T., Kocjan, A., Jevnikar, P., 2020. The effect of firing protocols on the resin-bond strength to alumina-coated zirconia ceramics. *Adv. Appl. Ceram. Struct. Funct. Bioceram.* 119, 267–275, Copyright Taylor & Francis.

terminal group, which allows the copolymerization with the resin. Today 10-MDP-based cements and primers are used for this purpose. The low viscosity of 10-MDP primers favors penetration into surface micro-porosities and bond resistance over time. In the other hand, 10-MDP-based viscous cement can bind to zirconia but are not able to, alone, maintain stable long-term adhesion, which is more susceptible to hydrolysis (Russo *et al.*, 2019).

Among surface roughening techniques the APA using silica modified alumina particles (i.e., the so-called Rocatec system) has been developed not only to enhance the surface roughness of zirconia but also to provide free silica groups to form the bond with the silane coupling agent. Although this bond is according to thermodynamic calculations more resistant to hydrolysis than the bond between zirconia and 10-MDP (Xie *et al.*, 2016), the effectiveness of APA using silica modified alumina particles has been questioned (Kern, 2015).

An alternative solution to the adhesion problem has recently been proposed by a non-invasive functionalization of the zirconia surface, by applying a thin (200–400 nm) nanostructured alumina coating consisting of interlocked 2D lamellae or nanosheets exhibiting a large surface area by which bonding to the substrate is significantly improved. The coating shows a uniform thickness and good surface coverage (Fig. 4(b) and (c)). It is almost insensitive to thermocycling and has the potential of durable improvement of the adhesive bond between the coated core material and the dental cements by a factor of 2–4, depending on the surface roughness of the substrate, the dental cement and the firing protocol used (Jevnikar *et al.*, 2010, 2012; Malgaj *et al.*, 2020).

Delamination and Chipping of the Veneered Overlayer

Chipping and fracture of veneering porcelain are commonly reported in all-ceramic zirconia restorations, which is reportedly higher than the chipping rate of porcelain bonded to metal-ceramic restorations. This could be ascribed to the higher chemical inertness, less favorable wetting ability and considerably lower thermal diffusivity of 3Y-TZP ceramics, as compared to metals. The thermal expansion mismatch and cooling rate-induced tempering of zirconia framework and veneering porcelain contribute to the formation of high tensile subsurface residual stresses in layers of porcelain which may result in unstable crackings or chippings, that are presumably contact-induced (Swain, 2010). Minor chipping damages can be temporarily repaired (Özcan, 2015; Özcan *et al.*, 2013), but in most cases, the whole restoration has to be replaced. Other causes for failures of all-ceramic FPDs are debonding, i.e., loss of coherence between the restoration and the abutment tooth, fracture of the framework, and delamination of the veneering porcelain. The fracture is due to the locally exceeded stress concentration in the framework, while the debonding and delamination are associated with the chemical inertness of the core material. Also worth mentioning is the problem that not only dental clinicians but also the producers of the zirconia blanks are facing. This is the lack of relevant standards and recommendations regarding the physical and chemical properties of 3Y-TZP ceramics for dental applications, i.e., considering specific clinical conditions in the aggressive environment of the oral cavity.

Aside of the several unsuccessful attempts to overcome the chipping problem by hot pressing or CAD/CAM machining and subsequent joining with 3Y-TZP core, the community geared toward a more radical but practical solution, i.e., toward porcelain-free, monolithic zirconia crowns and bridges, despite the risk of higher wear of the opposing tooth enamel and the direct exposure of the ageing-susceptible zirconia surface to the aggressive wet environment of the oral cavity. Nevertheless, the introduction of this conceptual idea was largely accepted in the dental community leading to wide production and application of the monolithic or full-contour zirconia ceramics for FPDs.

Translucency

In the quest towards highly translucent but stronger than glass-ceramics, new generation zirconia grades have been developed and commercialized recently. Due to the improved esthetics, monolithic restorations with only a thin, few microns thick, glaze coating layer (in visible regions) can be realized, allowing a further reduction of the restoration thickness. Moreover, pre-sintered blocks

are both available as pre-shaded in several tonalities and multilayered with gradients of chroma and different degrees of translucency. The benefit of the so-called “monolithic/full-contour” restorations allow decreasing the risks of chipping, the prosthetic cost and production time.

Zirconia ceramics with increased translucency can be realized in several ways: (1) refining the microstructure using (a) wet shaping techniques of zirconia nanopowders (Liu *et al.*, 2016) and/or (b) advanced sintering strategies (Xiong *et al.*, 2014; Kocjan *et al.*, 2015) and specific sintering additives, (2) grain boundary (microstructural) engineering by co-doping to control dopant segregation (Zhang *et al.*, 2015) (3) increasing the amount of cubic phase that ultimately increases grain size that also possesses considerably lower optically anisotropy (birefringence) (Zhang and Lawn, 2018).

All these strategies can be found in different commercial zirconias with a claimed improved translucency. In particular, we may now find novel yttria fully-stabilized grades with a higher content of yttria. However, not only do these microstructural variations imply substantial improvements in the overall optical performance of zirconia, but they also inevitably introduce noticeable changes in its mechanical properties and long-term stability (Camposilvan *et al.*, 2018).

Elastic Modulus and Hardness Mismatch

3Y-TZP hardness (12–14 GPa) is ~50% lower than of alumina, which is a clear advantage over alumina in the adjustments of occlusal surfaces of FPDs by grinding, finishing or polishing. In addition, the importantly lower hardness of zirconia should also reflect in a less severe impact of occlusal wear of opposing teeth, where the average hardness of enamel was reported to be between 3.4 and 4.8 GPa (Cuy *et al.*, 2002; Willems *et al.*, 1993). Moreover, due to the ability of zirconia ceramics to be finely polished, the occlusal wear appears to be negligible. The observed wear is even less damaging than in the case of feldspathic porcelain, lithium disilicate ceramics and enamel to enamel attrition (Chong *et al.*, 2015; Lawson *et al.*, 2014; Passos *et al.*, 2014; Wang *et al.*, 2012; Zhang *et al.*, 2019b). Such a positive outcome might be related to the ability of quasi-plastic deformation under mechanical wear as a result of evolved subsurface shear stresses triggering the *t-m* phase transformation (Luthardt *et al.*, 2004).

Another advantage of zirconia in relation to alumina is that its elastic modulus is much lower than that of alumina (200 GPa versus 380 GPa), which implies lower elastic stresses between the natural dentine and the prosthetic work. Still, the elastic modulus of zirconia is considerably higher than natural dentin that is demonstrated with posts-cores in endodontically treated teeth with insufficient tooth structure. Zirconia posts were introduced to replace esthetically unpleasant metal posts (Meyenberg *et al.*, 1995). However, the high elastic modulus of zirconia posts causes stress to be transferred to the less rigid dentin, thereby resulting in vertical root fractures (Mannocci *et al.*, 1999). A significantly improved fracture resistance and predominantly favorable failure modes were manifested, when restoring teeth with a prefabricated zirconia post and core system with a wide, retentive coronal shape and when the root post space is designed with 1–2-mm deep internal plateau (Fig. 5) (Jovanovski *et al.*, 2019).

Biocompatibility

Over the years, the tissue compatibility of zirconia ceramics has been evaluated extensively “in vivo” and “in vitro”. There has been an abundance of in vitro tests performed on different physical forms of zirconia (e.g., powders and dense ceramics), that showed no local or systemic cytotoxic effects or adverse reactions associated with zirconia. The “in vivo” bone formation adjacent to zirconia and the inflammatory response to zirconia have been shown to be satisfactory. However, initial results frequently showed

Fig. 5 (a) The internal plateau preparation in an extracted tooth mounted in resin and (b) after inserting the prefabricated zirconia post and core system in post space. Reproduced from (b) Jovanovski, S., Cotič, J., Kocjan, A., Oblak, Č., Jevnikar, P., 2019. Fracture resistance of endodontically treated maxillary incisors restored with zirconia posts: Effect of the internal plateau preparation. *Adv. Appl. Ceram.* 118, doi:10.1080/17436753.2018.1508625, Copyright Taylor & Francis.

the formation of connective tissue at the bone-ceramic interface before the implementation of surface roughening of zirconia implants improved bone-implant contact. Furthermore, microorganisms seem to adhere to zirconia to the same extent as to other materials. One can conclude that minor observed irritations may be attributed to mechanical irritation, e.g., from roughened surfaces. The mutagenic and cancerogenic *in vitro* tests on zirconia ceramics also showed the dearth of any similar reactions and no emergence of tumor cells (Piconi and Maccauro, 1999).

Zirconium is derived from Zircon (ZrSiO_4) or Baddeleyite. These minerals may contain a small amount of radioactive impurities. Thus, using zirconia in biomedical applications raised the question of the materials' safety. Zirconia-based medical devices are strictly regulated for radioactive decay (max. 0.2 Bq/g) by the ISO 13356 standard. The activity of uranium-radium and thorium radionuclides in different types of zirconia bioceramics was investigated by Porstendörfer *et al.* (1996). They showed that the estimated effective dose found was below the dose limit of 1 mSv/year. It was recently shown that the radioactive potential of zirconia dental ceramics is negligible compared to radioactive appliances in our environment (Bavbek *et al.*, 2014) obviously posing no risk to the patient.

Full-Contour Monolithic Zirconia and Minimally Invasive Dentistry

The development and commercialization of translucent zirconia dental ceramics allowed fabrication monolithic FPDs with innumerable advantages; these are the elimination of chipping risk, the satisfactory mechanical properties (compared to leucite and lithium disilicate glass-ceramics), the possibility of employing the CAD-CAM processing workflow (greater standardization and quality of results, with cost reduction), the possibility of manufacturing of thinner FPDs, and a more conservative dental preparation restricting within the principles of minimally invasive dentistry (Zhang and Lawn, 2018).

High-Translucency Zirconia (4Y, 5Y) Grades

Traditional partially-stabilized zirconia ceramics doped with 3 mol% yttria (3Y-TZP) have been shown to withstand the stresses superior to the highest biting forces. In the last few years, the progress in the manufacturing of zirconia ceramics with improved translucency and esthetic features have established new generations of high-, super- and ultra-translucent zirconia ceramics. This was mainly achieved by modifying the *t*- ZrO_2 matrix by adjusting the concentrations of minor elements, such as reducing the amount of alumina (Al_2O_3) and, more importantly, increasing the molar percentage (concentration) of yttria (Y_2O_3), up to 5 mol%, to the extent allowing its use in a monolithic form, e.g., single crowns, onlays, inlays, anterior cantilever resin-bonded bridges (Zhang and Lawn, 2018).

With that in mind, different zirconia generations have evolved historically. Zirconia materials can currently be divided into four types or generations according to their mechanical and optical properties (Güth *et al.*, 2019).

Biomedical grade 3Y-TZP

1st generation of dental zirconia is represented by the conventional biomedical grade 3Y-TZP. Since it is a birefringent material, the optical properties of 3Y-TZP are greatly influenced by the structure of the grain boundaries. Typically, the alumina content in this family of zirconia ceramics is around 0.25%, which is concentration high enough to facilitate the formation of isolated alumina grains in the 3Y-TZP matrix during sintering. As a consequence, light transmittance is hampered resulting in a high opacity and compromised visual appearance. Thus, 1st generation 3Y-TZP zirconia is not suitable material for monolithic use. In the past years, the main focus was to improve the optical properties, especially increasing the translucency.

Highly-translucent 3Y-TZP

A 2nd generation of highly-translucent zirconia ceramics was introduced around 2013 – a 3Y-TZP variant with lowered amount (~ 0.05 wt%) of alumina in the matrix. This way, the alumina grains do not form anymore in the ceramic matrix (Samodurova *et al.*, 2015b) resulting in a higher level of light transmission. The flexural strength remained high, and the *in-vitro* stability was sufficient allowing it to be predominantly used as a framework material for one- and multi-unit FDPs.

Ultra-translucent zirconia (stabilised with 5 mol% yttria)

The 3rd generation of dental zirconia ceramics was developed in 2015 labeled as ultra-translucent and is recommended for the production of single-tooth crowns and FDPs with up to three units in the anterior region. The increase of the yttria (Y_2O_3) content up to 5 mol% substantially increases the translucency (Fig. 6(a)), mainly because the resultant ceramic material with such an amount of yttria is closer to a more optically isotropic cubic symmetry form (or *t*- ZrO_2 with a much lowered tetragonality (Fujimori *et al.*, 2001)). The matrix grains are larger and less birefringent than the tetragonal grains; therefore, the light passes fewer boundaries that are also plan-parallel causing lower light scattering on passing through the material (Krell *et al.*, 2009). Besides a higher degree of translucency, the increase of the yttria content ultimately provides a genuinely LTD-resistant zirconia ceramics (Zhang *et al.*, 2016b).

The tremendously profitable improvements of gained by increasing the yttria content undoubtedly have a deleterious trade-off, i.e., they are mechanically weaker ceramic material due to the absence of the *t-m* transformation toughening (Fig. 6(b)). Compared

Fig. 6 (a) Comparison of translucency of various zirconia grades and lithium disilicate (LS2) ceramics in 0.5-mm thickness. (b) Weibull plots showing data for four-point bending strength of various grades of zirconia ceramics. Reproduced from (b) Zhang, F., Reveron, H., Spies, B.C., Van Meerbeek, B., Chevalier, J., 2019a. Trade-off between fracture resistance and translucency of zirconia and lithium-disilicate glass ceramics for monolithic restorations. *Acta Biomater.* 91, 24–34. doi:10.1016/j.actbio.2019.04.043, Copyright Elsevier.

to the lithium disilicate, the translucency of the 3rd zirconia generation is slightly lower, but the flexural strength and fracture toughness are higher (Zhang *et al.*, 2019a).

Super-translucent zirconia (stabilised with 4 mol% yttria)

Most recently, in 2017, the 4th generation of zirconia, known as super-translucent, was announced to increase the indication range for monolithic zirconia restorations, such as short-span multi-unit FDPs in the premolar region. Compared to the 3rd generation, the yttria content was reduced to 4 mol% (*t*-ZrO₂ polymorph), which led to an enhancement of the mechanical properties with a combined reduction in its optical properties. It is LTD resistant material owing to the absence of t-m process, whereas the improved strength and toughness in comparison to 5 mol% variant originate from the process of ferroelastic domain switching typically encountered in *t*-ZrO₂ (Hannink *et al.*, 2004; Virkar and Matsumoto, 1986; Mercer *et al.*, 2007).

Glazing and Staining

Milling of a presintered blank to full-contour has been established for monolithic zirconia restorations (Fig. 3(b)). In this way, the common use of a thick ceramic veneer layer can be avoided, but a thin stain and glaze coating layer still need to be applied to realize the overall appearance of monolithic crowns, inlays, onlays or veneers. Fine glass powder that may contain metal oxides as pigments is applied on zirconia surface and subsequently fired at temperatures between 550 and 900°C. The characteristic and smooth esthetic layer of overglaze is formed superficially on zirconia restoration. Glazing does appear to protect the first two zirconia generations against LTD in a humid oral environment (Oblak *et al.*, 2017).

However, it has been shown that glazed zirconia increases wear of antagonist teeth and also of restoration itself; the extent of wear of the antagonists was reported to be even higher than for the polished zirconia (Lawson *et al.*, 2014). Therefore, the occlusal surfaces of monolithic restorations in posterior regions should not be altered with glazing, unless esthetics is preeminent and that exposed, unglazed surfaces are carefully polished before use in order to reduce the wear of the enamel of the opposite teeth (Liu *et al.*, 2016).

Moreover, it was also shown that after long-term thermal and mechanical fatigue the glaze layer might represent the weakest link for crack initiation and propagation, which can dramatically affect the strength of FPDs. Studies have shown that the glazing significantly reduces the flexural strength of high translucent zirconia and that LTD decreased the flexural strength of glazed translucent (Nam and Park, 2018) and super-translucent zirconia (Lai *et al.*, 2017) indicating accumulating stress areas in the surface layers of the material. Furthermore, in a fractographic study of Oblak *et al.*, it was clearly indicated that the flaws and imperfections in the glaze layer or the glaze-zirconia interface depict the weakest spot of the glazed zirconia restorations where the initiation of the fracture presumably originates (Fig. 7) (Oblak *et al.*, 2017).

Self-Glazed Zirconia Ceramics

A new grade of self-glazed zirconia ceramics, based on 3Y-TZP system, with natural-looking, enamel-like surface finish has been recently developed to address the above-mentioned risks of glazing (Shen *et al.*, 2017). It requires no further need for veneering or glazing, thereby evading fragile interfaces (Fig. 8(a)). Moreover, beside rationalization, i.e., abolishing the need for glazing step

Fig. 7 SEM fractographic analysis of the monolithic 4-unit zirconia bridge overlaid with thin glaze layer after fracture in bending. Reproduced from (b) Wu, Z., Shi, A., Liang, Q., *et al.*, 2020. Aesthetic restoration of anterior teeth with monolithic self-glazed zirconia crowns via a completely digital workflow: A clinical case report. *Adv. Appl. Ceram.* 119, 291–296. doi:10.1080/17436753.2019.1690847, Copyright Taylor & Francis.

that is done in a dental laboratory, the precision additive 3D gel deposition fabrication allows full digitalized reconstruction approach (**Fig. 8(b)**), since it can be applied with slightest clinical adjustment (Liu *et al.*, 2016).

The reliability of self-glaze zirconia material was shown comparatively strong to conventional zirconia materials in crown and bridge restorations (Zhang *et al.*, 2017). Different from the rougher CAD/CAM milled zirconia, the self-glazed zirconia has very smooth surfaces that prevent excessive wear of antagonist teeth, which is similar to the polished surface. The improved esthetic appearance of self-glazed zirconia ensures its potential for direct clinical uses (Liu *et al.*, 2016).

Zirconia Oral Implantology

Oral implants to replace lost teeth were a big step forward in oral rehabilitation. With oral implants, the patients' comfort can be increased with implant-supported/-retained fixed/removable prosthesis (Heydecke *et al.*, 2005). Titanium is considered to be the material of choice for the fabrication of oral implants (Howe *et al.*, 2019). However, due to certain reasons, e.g., patient request,

Fig. 9 (a) A Y-TZP one-piece implant (ceramic_implant, Vitaclinical, Bad Säckingen, Germany), (b) an ATZ one-piece implant (Ziraldent, Metoxit, Thayngen, Switzerland) and (c) an ATZ two-piece implant (Zeramex XT, Dentalpoint AG, Spreitenbach, Switzerland).

esthetic concerns, health issues like titanium hypersensitivity, and more, zirconia ceramic implants are also being used in oral implantology today (Balmer *et al.*, 2020; Kohal *et al.*, 2020).

Zirconia-Based Implant Materials

In the beginning of the ceramic implant era, alumina was applied as a substrate for implant fabrication (Schulte, 1981). However, this material was too weak to withstand oral function over a longer period of time (De Wijs *et al.*, 1994). Furthermore, bone apposition (i.e., osseointegration) onto that material was not predictable. In the search of a “better” tooth-color-like ceramic material, zirconia was evaluated. Today, the ceramic materials which are possibly to be used for the fabrication of oral implants are 3Y-TZP (Balmer *et al.*, 2018), ATZ (Spies *et al.*, 2015), Ce-TZP (Lopez-Pérez *et al.*, 2017) or composite ceramics (Altmann *et al.*, 2017). In clinical investigations (Pieralli *et al.*, 2017; Roehling *et al.*, 2018), the dominant zirconia material so far is 3Y-TZP (Fig. 9(a)) followed by ATZ (Fig. 9(b)). Composite materials such as ceria-stabilized zirconia–alumina–aluminate composite ceramics are in the experimental stage.

Implant Systems – One/Two-Piece

Initially, zirconia ceramic implants were designed as one-piece implants because of fabrication and stability reasons. Therefore, most of the clinical investigations published so far were evaluating one-piece zirconia implants. The advantages of the one-piece implants are their excellent stability (high fracture resistance), good short- to mid-term clinical performance, low marginal bone loss, no abutment screw loss and no microgap between abutment and implant body possibly serving as bacterial reservoir leading to marginal periimplant soft tissue inflammation. The disadvantages of the one-piece implants are found in their versatility. The adaptation of the abutment part to the clinical situation is only possible through grinding which in the end might lead to stability reduction (Fig. 10).

The correct prosthetic position can be problematic, especially in areas with an increased inclination of the alveolar ridge. The prosthetic reconstructions of one-piece implants are generally regarded as limited. Due to the mentioned shortcomings of one-piece implants, two-piece implants were developed (Fig. 9(c)). They present an improved prosthetic versatility with the application of angulated abutments if needed. The reconstructions are usually screw retained (gold alloy, titanium alloy, carbon-reinforced PEEK) and can therefore be removed for any reasons without destroying those (Fig. 11).

Implant Stability

An expressed concern with ceramic implants is their long-term stability. Therefore, it is of utmost importance to evaluate fracture resistance in-vitro before launching an implant product on the market. Numerous reports have been published on the in-vitro stability of one- and two-piece zirconia oral implants which have been evaluated in a systematic review by Bethke and coworkers (Bethke *et al.*, 2020). From the included and evaluated publications, the authors came to several conclusions: one-piece implants are obviously more stable than two-piece implants. Regarding the material, implants made from 3Y-TZP seem to be less stable than implants fabricated from ATZ. In a systematic review on clinical studies, Roehling *et al.* (2018) found regarding implant stability that only one out of 510 commercially available implants evaluated fractured. This translates into an overall fracture rate of 0.20% which is comparable to the fracture rate of titanium implants (0.18%) (Jung *et al.*, 2012).

One-piece implants with a diameter of 4 or more mm seem to be stable enough to survive at least 5 years of clinical function (Kohal *et al.*, 2020; Balmer *et al.*, 2020). From the in-vitro investigations, these implants survived long-term artificial chewing and it is anticipated that these implants also withstand long-term clinical load.

Zirconia ceramic implants made from 3Y-TZP are prone to LTD (see above) and show *t-m* transformation already in the as-delivered state or after hydrothermal ageing (Fig. 12). LTD was initially discussed to reduce the stability of zirconia. However, regarding zirconia ceramic implants that have been hydrothermally treated and have shown (superficial) transformation, no decrease in fracture stability (Sanon *et al.*, 2013; Spies *et al.*, 2018, 2017) could be observed.

Fig. 10 (a) An ATZ one-piece implant in the anterior upper region after adaptation to the prosthetic needs. (b) Implant reconstructed with an all-ceramic crown (Ziraldent, Metoxit, Thayngen, Switzerland).

Fig. 12 (a) A 3Y-TZP implant that shows t-m transformation already in the as-delivered state. (b) A 3Y-TZP without a transformation zone when delivered.

Clinical Performance of Zirconia Oral Implants

Zirconia oral implants are evaluated in clinical investigations. The scientific interest in zirconia implants is reflected among else in the fact that many systematic reviews on this type of implant have been published ([Andreiotelli et al., 2009](#); [Vohra et al., 2015](#); [Haro Adanez et al., 2018](#); [Pieralli et al., 2017](#); [Roehling et al., 2018](#)). The more recent reviews concluded that commercially available implants show similar survival rates as titanium implants in short term with up to two to five years (one-year survival: 95%–98%). In addition, the marginal bone loss around zirconia oral implants is not different in comparison to titanium implants

for the same follow-up period (0.78–0.98 mm). It is noteworthy to state that most of the primary investigations were dealing with implants used for single crown or small bridge reconstructions. For larger reconstructions or removable prosthesis on zirconia implants no data is available and no information can be therefore given regarding survival rates.

The data for two-piece zirconia implants are considered as insufficient to date and therefore no conclusion on their (short- and mid-term) clinical behavior can be made.

Ce-TZP-Aluminate Pseudoplastic Ceramic Composite

Zirconia-based composites were developed to resist ageing (Reveron *et al.*, 2017; Palmero *et al.*, 2015). The laboratory investigations that have been performed were encouraging. Also, the biological testing with primary osteoblasts has shown positive results. Furthermore, in an animal model, it was shown that miniature implants made from one of those composites integrated well into rat femur (Altmann *et al.*, 2017). Additional preclinical research is necessary in order to be able to describe the mechanical, biological and clinical behavior of such ceramic composites.

Emerging Additive Manufacturing of Zirconia Dental Ceramics

Additive manufacturing (AM) or 3D printing of dental ceramics is a relatively new class of shaping technologies in which a zirconia part is directly generated from a digitally designed virtual 3D model by adding material layer upon layer, as opposed to subtractive manufacturing methodologies. Digital dentistry is reported to be one of the fastest-growing sectors of the AM technologies (Van Noort, 2012). Concerning dental materials that can be used in AM, polymers are the most studied and used ones, followed by metals. AM of ceramics is possible but issues with suitable surface finishing, mechanical properties and dimensional accuracy persist. However, compared to subtractive CAD/CAM machining, AM of ceramics reduces material waste and tooling stresses that are associated with the milling of ceramics. It also allows lower production costs compared to milling, faster production of customized dental pieces with complex details (e.g., intricate internal geometries and arbitrary angles), since they involve less manufacturing steps (Branco *et al.*, 2020). In most of the cases, AM of zirconia is used to obtain preliminary 3D structures in green state that are built from mixture powders with polymeric binder materials and need to be submitted to further steps of debinding and sintering.

The production of zirconia parts adopting different AM techniques has been the main focal point of some latter studies that investigated properties as density, porosity, surface roughness, microstructure, dimensional accuracy, morphology and mechanical behavior. It is possible to print zirconia components with mechanical properties close to milled zirconia (flexural strength 943 – 1154 MPa (Scheithauer *et al.*, 2015)), fracture toughness 3.9–6.7 MPa m^{1/2} (Branco *et al.*, 2020; Scheithauer *et al.*, 2015) and hardness 13.9 GPa (Xing *et al.*, 2017) and high dimensional stability (Osman *et al.*, 2017; Xing *et al.*, 2017). Overall, the preliminary results show that AM fabricated zirconia can be used in dental restorations such as ultra-thin occlusal veneers, with substantial advantages for processing (Branco *et al.*, 2020). However, besides the surface finish, the difficulties of the debinding process of the green part influence the consistency of the mechanical performance of 3D-printed zirconia.

Among many AM technologies available, the most promising remains to be VAT polymerization (Fig. 13), which can realize high precision and accuracy in the ranges of ten micrometers (Ioannidis *et al.*, 2020). VAT polymerization utilizes photopolymerization of a ceramic slurry to produce dense objects in a layer-by-layer fashion. Typical composition of ceramic suspension includes a monomer, photoinitiator, dispersants and solid ceramic loading of 40%–60% volume. As-printed green compacts are manufactured with a packing density of 55% theoretical density (TD), and it is possible to achieve densities exceeding 99% TD after sintering. The only restriction is imposed by the lengthy debinding step, that is diffusion-limited, thus depending on the thickness of the fabricated part. However, 3D printed zirconia may be regarded as a forthcoming material for the production of dental restorations.

Fig. 13 3D-printed by VAT polymerization occlusal veneer before removing the support structures resulting from the printing process, viewing (from left to right) from occlusal, inner surface, and after having removed the supporting structure. Mater.* 36, e109–e116. doi:10.1016/j.dental.2020.01.016, Copyright Elsevier.

The Outlook of Zirconia Ceramics for Dentistry

Dentistry has since the last decade been undertaking a major change of the workflow from the traditional manual dependent to novel digital technology, where zirconia, especially the full-contour monolithic variant, has proved the ability to realize complete digital workflow. Successful digitalization, however, requires immediate addressing of several issues; (1) the development of digital manufacturing technologies beyond the state-of-the-art for the fabrication of net-shape zirconia FPDs. Preferably, with no or only scarce manual work involved not having any decisive role in the determination of the final quality of the fabricated FPD. With this restriction in mind, AM technologies appear to take over the subtractive type of manufacturing processes. (2) Overcoming big challenge of realization of the optical appearance of the natural teeth; as optical appearance is generated by many physical properties, such as color, translucency, opalescence and surface roughness. (3) The “bioactivation” of an otherwise bio-inert zirconia surface for oral implantology, where hierarchical, multiscale surface texturing has emerged as a promising strategy for enhanced soft and hard tissue integration. Other issues, such as improving mechanical reliability, chemical stability, optical translucency and bonding strength with teeth, all have already been successfully addressed, still, an endless journey of additional optimization is to be expected to further optimize zirconia's clinical and biological experience.

Conclusions

The large research of the 3Y-TZP's low-temperature degradation (LTD) process initiated at the onset of the present millennium was followed by the development of new generations of zirconia ceramics systems to address the demanding needs of advanced dental materials. Zirconia dental ceramics had ever since emerged from the oblivion masked by the dramatic failure of femoral heads to become a dental ceramics of choice in modern restorative dentistry. Nowadays it is expanding clinical indications of tooth-colored, metal-free all-ceramic systems from crowns and bridges, orthodontic brackets, root posts and even implants, but also allowing the minimally invasive dentistry.

The evolution from veneer-overlaid zirconia FPDs to full contour monolithic restorations has increased the need for more translucent and LTD resistant zirconia ceramics. The transition to yttria, fully-stabilised zirconias` however need to carefully balance between the conflicting demands of the increasing the translucency (and LTD resistance) at the expense of losing beneficial mechanical properties at the absence of *t-m* transformation mechanism depending on the perceived clinical indication.

The advent of additive manufacturing of dental ceramics has very high expectations. Still there are issues to be resolved before the wasteful but very effective FPDs fabrication by CAD/CAM technology can be replaced. Yet the idea of the possibility to fabricate hybrid multilayered zirconia FPDs in restorative dentistry, where the core layer would be composed of a tougher more opaque zirconia variant to provide mechanical integrity, while the outer layer from highly translucent one for the increased esthetics in the region of incisive to mimic dentin and enamel, respectively, is now firmly placed on the horizon.

Subject Index

Note

This index is in letter-by-letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization, and it is arranged in set-out style, with a maximum of three levels of heading.

Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space).

Location references refer to the volume number, in bold, followed by the page number.

Page numbers followed by “*f*” and “*t*” refer to figures and tables, respectively.

W

wall slip 1:170

waste of electrical and electronic equipment (WEEE) 3:358

wastes, glass-ceramics from 2:721–722

radioactive product confinement 2:721–722

toxic wastes disposal and recovery 2:722–723

WAT *see* Water Adsorption Test (WAT)

Water Adsorption Test (WAT) 1:165

waveguides and applicators 1:330–331

- microwave generators 1:332
- multimode cavity 1:332
- temperature control in MW heating 1:332–333
- tunable single mode cavity 1:331–332

wavelength dispersive spectrometry (WDS) 1:656–657, 1:660

wavelength dispersive X-ray analysis 1:659–660

wave propagation

- in an ideal transparent refracting medium 2:659–660
- in vacuum 2:658–659
- in a weakly absorbing medium 2:660

WAXS *see* wide-angle X-ray scattering (WAXS)

WDS *see* wavelength dispersive spectrometry (WDS)

weak matrix concept (WMC) 2:270–271

weak phase object approximation (WPOA) 1:597

wear 2:427–428

wear and erosion resistant ceramic coatings 2:425

- nanocomposite hard coatings, formation of
- by mixing processes 2:433–435
- by post-deposition annealing 2:435–437

physical vapor deposition (PVD) methods 2:430–431

- energy delivered to the growing film 2:431
- mixing processes 2:431–432

structure and property control in hard coatings 2:430

tribology 2:425–427

- erosion 2:428–429
- friction 2:425–427
- wear 2:427–428

wear reduction 2:429–430

wear and erosion resistant ceramic materials 2:416

- alumina based ceramics 2:418
- boron carbide materials 2:421
- ceramic materials and ceramic matrix composites, development of 2:416–418
- high entropy ceramics 2:422
- silicon carbide based ceramics 2:420–421
- silicon nitride based ceramics 2:419–420
- titanium-diboride based ceramics 2:421–422
- wear and erosion evaluation 2:416
- zirconia based ceramics 2:418–419

wear reduction 2:429–430

WEEE *see* waste of electrical and electronic equipment (WEEE)

Weibull modulus 3:772

Weibull plot 3:786–787

Weibull theory 1:811

Werthamer-Helfand-Hohenberg (WHH) behavior 3:167

wet bag route 1:138

wet-chemically prepared films 3:220

wet chemical routes, synthesis of ceramic powders by 1:27

- bulk liquid phase, chemistry in 1:27–28
- precipitation 1:30–31
- sol-gel synthesis 1:27–28

droplet, chemistry in 1:35–36

- emulsion and microemulsion synthesis 1:35–36
- spray-based syntheses 1:37–38

heterogeneous phases, chemistry between 1:31–32

- molten salt synthesis 1:33–34
- solvothermal synthesis 1:31–32

wettability 3:702

wetting 1:114, 2:400

WHH behavior *see* Werthamer-Helfand-Hohenberg (WHH) behavior

whisker 1:903–904, 2:231

whisker composites, properties of 2:230–231

- creep behavior 2:231
- SiC(W)
- alumina composites 2:230–231
- matrices composites 2:231

whisker reinforcement 2:228

whitewares 2:67–68
